

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

THE
SCIENCE AND ART
OF
SURGERY.

A TREATISE ON SURGICAL INJURIES, DISEASES,
AND OPERATIONS.

BY
JOHN ERIC ERICHSEN, F.R.S., LL.D., F.R.C.S.,
SURGEON EXTRAORDINARY TO HER MAJESTY THE QUEEN; EX-PRESIDENT OF THE ROYAL COLLEGE
OF SURGEONS OF ENGLAND AND OF THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY;
EMERITUS PROFESSOR OF SURGERY AND OF CLINICAL SURGERY IN UNIVERSITY
COLLEGE; CONSULTING SURGEON TO UNIVERSITY COLLEGE HOSPITAL,
AND TO MANY OTHER MEDICAL CHARITIES.

EIGHTH EDITION.

REVISED AND EDITED BY
MARCUS BECK, M.S. AND M.B. LOND., F.R.C.S.,
SURGEON TO UNIVERSITY COLLEGE HOSPITAL; AND PROFESSOR OF CLINICAL SURGERY IN
UNIVERSITY COLLEGE, LONDON.

WITH NINE HUNDRED AND EIGHTY-FOUR ENGRAVINGS ON WOOD.

VOL. II.

PHILADELPHIA:
LEA BROTHERS & CO.
1885.

"They be the best Chirurgeons which being learned incline to the traditions of experience, or being empirics incline to the methods of learning."

BACON on Learning.

CONTENTS OF THE SECOND VOLUME.

DIVISION THIRD.

SURGICAL DISEASES.

(CONTINUED.)

CHAPTER XXXVII.—SURGICAL DISEASES OF THE SKIN AND ITS APPENDAGES.

	PAGE
DISEASES OF THE APPENDAGES OF THE SKIN—Diseases of the Nails—Onychia— Simple—Syphilitic—Ingrowing of the Nail—Hypertrophy of Toe-nail	33-35
DI-EASES OF THE SKIN—Lupus—Varieties—Lupus Erythematosus—Lupus Vul- garis or Lupus—Causes—Prognosis—Diagnosis—Treatment—Rodent Ulcer— Symptoms—Diagnosis—Pathology—Treatment—Cancer of the Skin—Primary Cancer—Secondary Cancer—Sarcomata of the Skin—Alveolar Sarcoma— Simple Tumors of the Skin—Fibroma—Keloid—False Keloid—Osteomata —Adenoma—Moles—Papillomata, or Warts—Corns—Perforating Ulcer of Foot	35-48

CHAPTER XXXVIII.—DISEASES OF THE NERVOUS SYSTEM.

NEURITIS—Symptoms—Treatment	48
NEURALGIA—Symptoms—Diagnosis—Treatment—Acupuncture—Stretching the Sci- atic Nerve	48-50
NEURALGIA—Symptoms—Situations—Causes—Diagnosis—Treatment—Stretching of the Affected Nerve—Section of the Affected Nerve—Facial Neuralgia	50-56
MUSCULAR TIC—Clonic Torticollis	57
TRAUMATIC PARALYSIS—Rheumatic Paralysis, or Paralysis from Exposure to Cold—Treatment	57-58
NEUROMA—Structure—Traumatic Neuroma—Treatment	58-60
TETANUS—Causes—Period of Occurrence—Forms—Symptoms—State of Nerves— Seat of Injury—Pathological Conditions in Spinal Cord—Treatment	60-68

CHAPTER XXXIX.—DISEASES OF THE LYMPHATIC SYSTEM.

INFLAMMATION OF THE LYMPHATIC VESSELS—Lymphangitis, or Angioloecitis— Causes—Morbid Anatomy—Symptoms—Results—Diagnosis—Treatment	68-70
VARIX OF THE LYMPHATIC VESSELS—Occurrence—Treatment	70
ELPHANTIASIS OF THE LEGS AND SCROTUM—Treatment	70-72
LYMPHADENITIS, OR INFLAMMATION OF LYMPHATIC GLANDS—Pathological Anatomy—Symptoms—Treatment	72-76
LYMPHADENOMA—Removal	76

CHAPTER XL.—DISEASES OF VEINS.

	PAGE
VENOUS THROMBOSIS—Causes—Process of—Fate of the Thrombus—Effects—Symptoms—Treatment	77-83
PHLEBITIS—Causes—Pathological Anatomy—Symptoms—Treatment	83-86
VARICOSE VEINS, OR VARIX—Definition—Causes—Locality—Morbid Anatomy—Appearances and Symptoms—Progress and Effects—Treatment—Obliteration of Varicose Veins	86-91

CHAPTER XLI.—ANEURISM BY ANASTOMOSIS, AND NÆVUS—HEMORRHAGIC DIATHESIS.

ANEURISM BY ANASTOMOSIS—Nature—Diagnosis—Treatment	92-98
NÆVUS—Capillary—Venous or Cavertous—Prognosis—Treatment—Operations—Obliteration—Nitric Acid—Galvanic Cautery—Galvano-puncture—Ligature—NÆVI IN SPECIAL SITUATIONS—Scalp—Fontanelle—Face—Eyelids—Nose—Cheeks—Lips—Tongue—Penis—Vulva—Extremities, Neck, and Trunk—Nævoid Lipoma	98-105
HEMORRHAGIC DIATHESIS, OR HÆMOPHILIA—Causes—Pathology—Treatment	105-108

CHAPTER XLII.—DISEASES OF ARTERIES.

ARTERITIS—Acute—Traumatic—Arteritis by Extension—Embolio—Acute Endarteritis—Arteritis Deformans, or Atheroma—Nature and Causes of—Effects—Arteritis Obliterans—Endarteritis Proliferans—Periarteritis	108-116
PRIMARY DEGENERATIONS OF ARTERIES—Fatty Degeneration—Calcification—Ossification—Effects of Disease—Ulceration—Spontaneous Rupture—Contraction and Occlusion	116-121

CHAPTER XLIII.—ANEURISM.

ANEURISM defined—Causes—Classification—Fusiform or Tubular Aneurism—Sacculated Aneurism—True—False—Dissecting Aneurism—Formation of an Aneurism—Structure—Pressure-effects—Number—Duration—Symptoms of External Circumscribed Aneurism; of Diffuse Aneurism—Diagnosis—Terminations—Spontaneous Cure—Causes of Death from Aneurism—Constitutional or Medical Treatment—Local Treatment	122-141
SURGICAL TREATMENT OF ANEURISM.—LIGATURE—Situation—Ligature on both Sides of Sac—Ligature on Cardiac side of Aneurism—Distal Ligature—Indications and Contra-indications of Ligature—Accidents after Ligature—Secondary Hemorrhage—Continuance or Return of Pulsation—Secondary Aneurism—Treatment of Recurrent Pulsation—Suppuration and Sloughing of Sac—Gangrene—Causes—Treatment.—COMPRESSION BY INSTRUMENTS—Principle—Circumstances influencing Success—Application of Compressor—Effects—Duration of Treatment—Applicability—Digital Compression—Esmarch's Elastic Bandage—Flexion—Acupressure—Manipulation—Galvano-puncture—Injection with Perchloride of Iron—Hypodermic Injection of Ergotin—Introduction of Foreign Bodies—Acupuncture	141-171
ARTERIO-VEINOSUS ANEURISM	172

CHAPTER XLIV.—ANEURISMS OF THE THORAX, HEAD AND NECK, AND UPPER EXTREMITY.

	PAGE
THORACIC AORTA—Symptoms—Auscultatory Signs—Pressure-effects—Pulsation and Tumor—Treatment	173-180
INNOMINATE ARTERY—Symptoms—Pressure-effects—Prognosis—Diagnosis—Treatment—Ligature of Subclavian only—Of Carotid only—Of Subclavian and Carotid—General Remarks on the Operation	180-188
CAROTID ARTERY—Aneurismal Varix of Carotid Artery and Jugular Vein—Spontaneous Aneurism of Carotid—Symptoms—Diagnosis—Treatment—Digital Compression—Ligature of Carotid—Effects on Brain—Table of Cases of Ligature of both Carotids—Effects on Lungs—Ligature of Carotid on Distal Side—Table	188-200
INTERNAL CAROTID ARTERY—Extracranial Aneurism—Treatment	200-201
INTRACRANIAL ANEURISM—Causes Pathology—Pressure-effects—Symptoms—Causes of Death—Treatment	201-206
ORBITAL ANEURISM—Erroneous Opinion regarding—Causes—Symptoms—Prognosis—Pathology—Diagnosis—Treatment	206-210
SUBCLAVIAN ARTERY—Symptoms—Diagnosis—Results—Treatment—Ligature of the Brachio-cephalic Artery—Table of Cases—Ligature of Subclavian on Tracheal Side—Table—Compression of Artery on Distal Side—Distal Ligature of Subclavian beyond the Scaleni—Amputation at Shoulder-joint, and Distal Ligature—Ligature of Vertebral Artery	210-221
AXILLARY ARTERY—Symptoms—Diagnosis—Treatment—Ligature of the Subclavian in Third Part of Course—Accidents during Ligature of the Third Part of the Subclavian—Ligature behind the Scalenus Anticus—Results of Ligature of the Subclavian—Suppuration of the Sac—Secondary Hemorrhage—Gangrene of Hand and Arm—Treatment of Inflamed Axillary Aneurism threatening Suppuration—Ligature of Axillary Artery	221-237
ARM, FOREARM, AND HAND—Rarity of Spontaneous Aneurism—Treatment—Ligature of the Brachial Artery—Ligature of Radial and Ulnar Arteries	237-241

CHAPTER XLV.—ANEURISMS OF THE ABDOMEN AND LOWER EXTREMITIES.

ABDOMINAL AORTA AND ITS BRANCHES—Symptoms—Diagnosis—Treatment—Compression of Abdominal Aorta	241-244
INGUINAL ANEURISM—Symptoms—Diagnosis—Treatment—Ligature of External Iliac Artery—Abernethy's Modified Operation—Cooper's Method—Results—Ligature of Common Iliac—Results—The Old Operation—Treatment by Compression—Ligature of Aorta—Aneurism of the Internal Iliac and its Branches—Gluteal and Sciatic Aneurisms—Ligature of Internal Iliac	244-255
FEMORAL AND POPLITEAL ANEURISMS—Aneurism of Deep Femoral Artery—Aneurism of the Superficial Femoral and Popliteal Arteries—Symptoms—Diagnosis—Treatment—Compression—Flexion—Ligature of Common Femoral—Of Superficial Femoral—Results—Accidents attending Operation—Wound of Femoral Vein—Secondary Hemorrhage—Gangrene—Return of Pulsation in Sac—Secondary Aneurism—Ligature of Femoral Artery in the Middle of the Thigh—Ligature of External Iliac in Popliteal Aneurism—Double Popliteal Aneurism—Diffused Popliteal Aneurism—Amputation for Diffused Popliteal Aneurism	255-268

	PAGE
ANEURISM OF THE TIBIAL ARTERIES—Ligature of Popliteal Artery—Of Posterior Tibial—Of Anterior Tibial—Of Arteria Dorsalis Pedis—Of Peroneal Artery	268-271

CHAPTER XLVI.—INFLAMMATION OF BONE AND ITS EFFECTS.

GENERAL PATHOLOGY OF INFLAMMATORY AFFECTIONS OF BONE—Inflammatory Processes in the Periosteum—Affecting Compact Tissue—In the Medulla of Long Bones—In the Cancellous Tissue	272-283
PERIOSTITIS—Symptoms—Treatment	283-284
CHRONIC OSTEITIS AND PERIOSTITIS—Symptoms—Treatment—Linear Osteotomy	284-285
OSTEITIS DEFORMANS—Microscopic Examination	285-286
CHRONIC ABSCESS OF BONE—Causes—Symptoms—Treatment	286-289
DIFFUSE SEPTIC OSTEOMYELITIS—Symptoms—Treatment	289-291
ACUTE NECROSIS—Symptoms—Pathology—Results—Diagnosis—Prognosis—Treatment	292-294
CARIES—Definition—Causes—General Appearances—Situation—Symptoms—Treatment—Operations on Carious Bone	294-300
NECROSIS—Nature—Causes—Characters—Peripheral and Central—Sequestrum—Symptoms—Separation of the Dead Bone—Exfoliation—Reparative Process—Treatment—Removal of the Sequestrum—Instruments—Amputation—Resection—Necrosis of the Sternum, Scapula, or Pelvis—Cranial Bones—Patella—Ribs	300-311

CHAPTER XLVII.—STRUCTURAL CHANGES IN BONE AND TUMORS OF BONE.

HYPERTROPHY—True Hypertrophy—Inflammatory Hypertrophy—Increased Length.—ATROPHY—Arrested Growth	312-313
RICKETS—Causes—Symptoms—Progress and Prognosis—Pathology—Treatment	313-317
MOLLITIES OSSIUM: OSTEOMALACIA—Nature—Cause—Seat of the Disease—State of Urine—Symptoms—Diagnosis—Treatment	317-319
TUMORS OF BONE—Exostosis—Varieties—Symptoms—Treatment—Enchondromata or Cartilaginous Tumors—Fibroma—Cystic Tumors—Structure—Treatment—Hydatids.—SARCOMATA OF BONE.—PRIMARY MALIGNANT DISEASE—Central—Peripheral—Situations—Symptoms—Diagnosis—Treatment.—SECONDARY SARCOMATA.—TRUE CANCER OR CARCINOMA—Epithelioma.—PULSATING TUMORS—Situation—Symptoms—Treatment	319-331

CHAPTER XLVIII.—DISEASES OF JOINTS.

SYNOVITIS—Causes—Pathology—Symptoms—Acute Synovitis—Chronic Synovitis—Hydrarthrosis—Terminations—Treatment	332-336
ACUTE ARTHRITIS—Situations—Symptoms—Suppuration—Diagnosis—Pathology—Nature of Changes in Cartilage—Destruction of Cartilage from Synovial Disease—From Disease of Bone—Causes and Varieties—Repair—Treatment	336-348
CHRONIC STRUMOUS ARTHRITIS, OR WHITE SWELLING—Symptoms—Pathological Changes—Treatment	348-353

	PAGE
CHRONIC RHEUMATIC ARTHRITIS—Nature—Symptoms—Causes—Treatment—	
Chronic Rheumatoid Arthritis of Hip—Pathological Changes—Diagnosis—	
Chronic Rheumatoid Arthritis of Lower Jaw—Of Shoulder	353-358
ANKYLOSIS OR STIFF JOINT—Incomplete or Fibrous Ankylosis—Complete or	
Osseous Ankylosis—Treatment	358-361
LOOSE CARTILAGES IN JOINTS—Warty Condition of Synovial Membrane—Loose	
Cartilages—Characters—Symptoms—Diagnosis—Treatment	361-364
NEURALGIA OF JOINTS—Symptoms—Causes—Treatment	364-365

CHAPTER XLIX.—EXCISION OF JOINTS.

HISTORY—Indications for Excision—Conditions of Success—Repair after Ex-	
cision—Instruments—Operation	366-373
EXCISIONS IN THE UPPER EXTREMITY.—SHOULDER-JOINT—For Disease—Partial	
Excision—Complete Excision—Result—For Compound and Comminuted	
Fracture.—SCAPULA—Entire—Partial—Operation—Result.—CLAVICLE.—	
ELBOW-JOINT—For Strumous Diseases—For Ankylosis—For Compound	
Fracture or Dislocation—Operation—Results.—ULNA OR RADIUS—Ole-	
cranon.—WRIST—Lister's Operation.—HAND—Excision of Fingers and	
Metacarpal Bones	373-393
CONSERVATIVE SURGERY OF THE LOWER EXTREMITY.—HIP-JOINT.—KNEE—	
Operation—Selection of Cases for Excision—Results.—BONES OF THE LEG.—	
FOOT—Progress of Conservative Surgery—Conditions demanding Excision—	
Tarsal Bones—Os Calcis—Operation—Subperiosteal Excision—History and	
Results—Astragalus—Cuboid Bone—Scaphoid—Cuneiform Bones—Several	
Tarsal Bones—Malleoli—Metatarsal Bones—Toes	393-414
AMPUTATION IN JOINT DISEASES—Circumstances influencing Mortality	414-416

CHAPTER L.—DISEASES OF THE SPINE.

SPINA BIFIDA—Characters—Prognosis—Treatment	416-419
CARIES OF THE SPINE.—ANGULAR CURVATURE.—POTT'S DISEASE—Pathology	
—Symptoms—Paraplegia—Pleuritic Attacks—Abscess—Diagnosis—Pro-	
gnosis—Treatment	419-435
DISEASE OF THE CERVICAL SPINE—Diseases of the Atlas, Axis, and Occiput—	
Treatment	435-436
OTHER DISEASES OF THE SPINE—Gummata—Rheumatoid Arthritis—Tumors	437

CHAPTER LI.—DISEASES OF THE SACRO-ILIAC JOINT.

SACRO-ILIAC DISEASE—Nature—Pathology—Symptoms—Pain—Swelling—	
Lameness—Alteration in Limb—Abscess—Prognosis—Diagnosis—Treat-	
ment	437-442

CHAPTER LII.—DISEASES OF THE HIP-JOINT.

HIP-JOINT DISEASE—Characters—Forms of the Disease—General Phenomena—	
Pain—Attitude—Limitation of Movement—Suppuration—Sinuses—Disloca-	
tion—Ankylosis—Pathology and Symptoms of the Various Forms.—	
ARTHRITIC COXALGIA—Symptoms—Results.—CHRONIC STRUMOUS ARTH-	
RITIS.—WHITE SWELLING.—FEMORAL COXALGIA—Symptoms—Pathology	
—ACETABULAR COXALGIA—Symptoms—Prognosis of Hip-joint Disease—	
Life—Utility of the Limb—Diagnosis of Coxalgia—Treatment	442-461

	PAGE
EXCISION OF THE HEAD OF THE THIGH-BONE AND OF THE HIP-JOINT—History—Cases requiring Operation—In Arthritic Coxalgia—In Femoral Coxalgia—In Acetabular Coxalgia—Removal of the Diseased Acetabulum and Pelvic Bones—Methods of Operating—Results.—DISEASE OF THE GREAT TROCHANTER.—AMPUTATION IN DISEASE OF THE HIP-JOINT	461-471
ANKYLOSIS OF HIP-JOINT—Operation for Osseous Angular Ankylosis—Cross or Scissor-legged Deformity	471-475

CHAPTER LIII.—DISEASES OF SYNOVIAL MEMBRANES, AND OF MUSCLES.

DISEASES OF BURSEÆ—Situations in which Bursæ exist—Morbid Alterations.—DISEASES OF THE BURSA PATELLÆ—Inflammation—Suppuration—Disease of the Patella—Sloughing of the Bursa Patellæ—Enlargements—Housemaid's Knee—Treatment—Chronic Enlargement—Solid Tumors—Treatment—DISEASES OF OTHER BURSEÆ.—BUNION—Treatment	475-483
DISEASES OF SHEATHS OF TENDONS—Ganglion—Simple Ganglion—Treatment—Tenosynovitis—Treatment—Compound Ganglion—Treatment	483-485
DISEASES OF MUSCLES—Fatty Degeneration—Ossification—Inflammatory Affections—Syphilitic Disease—Tumors—Treatment	485-488

CHAPTER LIV.—DEFORMITIES.

LATERAL CURVATURE OF THE SPINE—Nature—Mechanism—Kyphosis and Lordosis—Causes—Signs of Lateral Curvature—Treatment of Lateral Curvature—Recumbent Position—Mechanical Contrivances—Treatment of Posterior Excursion—Of Posterior Incurvation	489-495
DEFORMITIES OF THE NECK AND LIMBS—Causes—Treatment—Tenotomy—Repair in Divided Tendons	495-499
DEFORMITIES AFFECTING THE FACE AND NECK—Wry-neck—Nature—Causes—Treatment	499-501
DEFORMITIES OF THE ARM AND HAND—Contraction of the Arm—Straight Ankylosis—Acquired Contraction of Muscles of Forearm—Paralysis of Extensors and Supinators—Club-hand—Arthritis Deformans of Hand—Contraction of the Fingers—Pathology—Treatment—Congenital Deformities of Fingers and Hand	501-508
DEFORMITIES OF THE LEG AND FOOT—Knock-knee—Treatment—Antiseptic Osteotomy—Contraction of the Knee-joint—Varieties—Causes—Contraction from Nervous Irritation—Treatment—Contraction from Inflammation of Knee—Chronic Contraction—Contraction from Ligamentous Consolidation—Treatment—Contraction of Hamstrings—Division of Hamstring Tendons—Contraction with Lateral Displacement—Treatment—Osseous Ankylosis of Knee—Deformities of the Bones of lower Limb from Rickets—Club-foot—Varieties—Pathological Changes—Talipes Equinus—Treatment—Talipes Calcaneus—Treatment—Talipes Varus—Treatment—Talipes Valgus—Treatment—Spurious Talipes Valgus—Hollow Club-foot—Contraction of the Plantar Fascia—Contraction of One Toe—Supernumerary and Webbed Toes—Congenital Hypertrophy of Toes and Foot—Weak Ankles	508-529

CHAPTER LV.—DISEASES OF THE HEAD AND NECK.

SCALP AND SKULL—Pachydermatous Tumor of Scalp—Fungus of the Dura Mater—Nature—Symptoms—Treatment—Fungus of the Skull—Congenital Hernia of the Membranes of the Brain—Tapping the Head	530-532
---	---------

	PAGE
Langenbeck's and Ollier's Modifications—Fistulous Openings through Nasal Bones—Operation for Depressed Nose	598-604
PLASTIC SURGERY OF THE LIPS —Harelip—Single and Double—Median Fissure—Age for Operation—Objects of Operation—Operation for Single Harelip—Operation for Double Harelip—Treatment by Simple Suture—Congenital Transverse Fissures of Cheeks—Cheiloplasty—Buchanan's Operation for Restoring Lower Lip.	604-614
PLASTIC SURGERY OF THE PALATE —Age for Operation—Staphyloraphy—Ferguson's Operation—Pollock's Operation—Uranoplasty—Perforation of the Hard Palate	614-619

CHAPTER LVIII.—DISEASES OF THE MOUTH AND THROAT.

TONGUE —Tongue-tie—Hypertrophy and Prolapsus—Glossitis—Abscess—Chronic Superficial Glossitis—Psoriasis, Leucoplakia—Prognosis—Treatment—Aphthæ—Simple Ulceration—Tubercular Ulcer—Syphilitic Gummata—Tumors—Nævus and Aneurism by Anastomosis—Cancer of Tongue—Nature—Diagnosis—Treatment—Division of Gustatory Nerve—Ligature of Lingual Artery—Operations on the Tongue—Excision of a Small Part—Strangulation by Ligature—Excision of Whole or Large Portion—Application of Écraseur—Submental Operation—Excision after Division of Lower Jaw—Hemorrhage During Excision—After-treatment—Accidents after Operation—Comparison of Methods of Operating—Results—Effect of Removal of Tongue on Speech—Cysts in Floor of Mouth—Salivary Calculi	619-641
PALATE, UVULA, AND TONSILS —Hard Palate—Soft Palate—Elongation of the Uvula—Tonsillitis or Quinsy—Treatment—Enlargement of the Tonsils—Treatment—Excision of Tonsils—Malignant Tumors	641-646
DISEASES OF THE PHARYNX —Syphilitic Affections—Erysipelatous Pharyngitis—Abscess—Treatment—Tumors	646-647
STRICTURE OF THE ŒSOPHAGUS —Conditions producing Dysphagia without Stricture—Forms of Stricture—Hysterical or Spasmodic—Fibrous—Cancerous—Treatment—Gastrostomy	647-654
DISEASES OF THE LARYNX —The Laryngoscope—Laryngitis—Varieties—Acute Catarrhal Laryngitis—Symptoms—Treatment—Acute Edematous Laryngitis—Symptoms—Diagnosis—Treatment—Chronic Laryngitis—Varieties—Simple—Chronic—Treatment—Local Medication of Larynx—Syphilitic Laryngitis—Diagnosis—Treatment—Tubercular Laryngitis—Diagnosis—Treatment—Complications of Chronic Laryngitis—Nervous Affections of Larynx—In Children—In Adults—Paralysis of the Larynx—Tumors of Larynx—Thyrotomy—Malignant Tumors—Extirpation of Larynx	654-668

CHAPTER LIX.—OPERATIONS ON THE AIR-TUBE AND ON THE CHEST.

LARYNGOTOMY AND TRACHEOTOMY —Conditions requiring Operation—Opening the Windpipe in Membranous Laryngitis—In other Forms of Laryngeal Obstruction—Necessity for Promptitude—Operations—Conditions requiring Operation—Laryngotomy—Tracheotomy—Difficulties—Exposing the Trachea—Hemorrhage—Opening the Trachea—Introduction of Tube—Trachea-tubes—Tracheotomy in Children—Comparison of Laryngotomy and Tracheotomy—After-treatment of Laryngotomy and Tracheotomy	669-688
SURGICAL OPERATIONS ON THE CHEST —Tapping the Pleural Cavity—Surgical Treatment of Empyema	688-689
TAPPING PULMONARY CAVITIES —Operation—Tapping the Pericardium	689-691

CHAPTER LX.—DISEASES OF THE BREAST.

	PAGE
DISEASES OF THE BREAST—Ages at which they occur	692
ANOMALIES OF DEVELOPMENT—Absence of Breast—Supernumerary Breasts and Nipples	692-698
NEURALGIA—Symptoms—Diagnosis—Treatment	698
HYPERTROPHY—Simple—Treatment	698-694
ABNORMAL CONDITIONS OF THE LACTEAL SECRETION—Absence—Excessive Flow—Lacteal Tumor—Treatment	694-695
INFLAMMATION OF THE BREAST—Varieties—Of Nipple and Areola—Treatment—Eczema of Nipple—Abscess of Areola—Milk-abscess—Inflammation and Abscess in Subcutaneous Areolar Tissue—Inflammation of Mammary Gland—Inflammation in Areolar Tissue between the Mamma and Pectoral Muscle—Treatment—Chronic Inflammation—Chronic Interstitial Mastitis—Chronic Abscess—Diffused—Treatment—Encysted—Diagnosis—Treatment—Tubercle—Syphilitic Disease of Mamma	695-701
TUMORS OF THE BREAST	701
NON-MALIGNANT TUMORS—Retention—Serous—Hydatid Cysts—Lipoma—Fibroma—Chondroma and Osteoma—Adeno-fibroma—Adeno-sarcoma—Painful Mammary Tumor—Treatment of Adeno-fibroma and Adeno-sarcoma—Cysto-sarcoma—Sarcomata—Diagnosis—Treatment—Sanguineous Cysts—Tumors containing Fœtal Remains	701-712
CANCER OF THE BREAST—Varieties—Scirrhus—Symptoms—Implication of Skin—Pain—Retraction of Nipple—Implication of Axillary Glands and Viscera—Constitutional Cachexy—Duration of Disease—Structure of Scirrhus—Encephaloid—Colloid—Duct-cancer—Causes of Cancer of Breast—Sex—Age—Injuries—Inflammation—Eczema of Nipple—Diagnosis—Treatment—Compression—Caustics—Operation—Question of Relapse—Prolongation of Life by Operation—Cases Unfit for Operation—Doubtful Cases—Cases Favorable for Operation—Return of Cancer after Operation—Amputation of the Breast—Mortality after—Axillo-mammary Cancer	712-732
DISEASES OF THE MALE BREAST—Scirrhous Cancer	732-738
AXILLARY TUMORS—Strumous Disease of Axillary Glands—Simple Tumors—Lymphadenoma of Axillary Glands—Fibromata—Sarcomata	738-784

CHAPTER LXI.—DISEASES OF THE ABDOMEN.

INTRODUCTORY REMARKS—Operative Treatment of Diseases of the Abdominal and Pelvic Viscera—Septic Peritonitis and Septicæmia—Shock after Operations—Hemorrhage	735-739
HERNIA defined—Structure—Sac—Neck—Body—Contents—Enterocœle—Epiplœcœle—Entero-epiplœcœle—Adhesions—Fluid—Hydrocœle of Hernial Sac—Loose Foreign Bodies in Sac—Signs of Hernia—Intestinal Hernia—Omental Hernia—Cæcal Hernia—Hernia of Bladder, or Cystocœle—Exciting Causes—Predisposing Causes—Sex—Age—Occupation—Other Causes—Conditions presented by Hernia	739-744
REDUCIBLE HERNIA—Definition—Application of Truss—Radical Cure of Hernia—Wutzer's Operation—Wood's Operation	744-751
IRRREDUCIBLE HERNIA—Causes of Irreducibility—Symptoms—Treatment—Inflamed Irreducible Hernia—Treatment—Incarcerated Hernia—Treatment	751-758

STRANGULATED HERNIA—Definition—Mechanism of Strangulation—Seat of Stricture—Local Effects of Strangulation—Inflammation of Gut after relief of Strangulation—Symptoms—Local Signs—Constitutional Symptoms—Modifications of Symptoms—Diagnosis—Treatment—Taxis—Auxiliary Measures—Persistence of Symptoms after Reduction—Treatment	751-763
OPERATION FOR STRANGULATED HERNIA—Operation in which the Sac is opened—Exposure of the Sac—Opening the Sac—Division of the Stricture—Reduction—Treatment of the Sac—Treatment of the Wound—After-treatment—Accidents and Modifications of the Operation—Peritonitis—Acute Catarrhal Inflammation—Management of Congested Intestine—Of Tightly Constricted Intestine—Of Gangrenous Intestine—Of Adhesions—Of Omentum—Wounds of the Intestine—Wounds of Arteries—Sloughing of the Sac—Artificial Anus and Fecal Fistula—Treatment—Operation without Opening the Sac—Reduction in Mass—Causes—Symptoms—Treatment—Hydrocele of the Hernial Sac	763-783

CHAPTER LXII.—SPIXIAL HERNIE.

INGUINAL HERNIA—Varieties—Oblique—Coverings—Relations—Direct—Coverings—Relations—Incomplete or Interstitial—Double—in Females, Signs—Diagnosis—Treatment—Operation—Seat of Stricture—Hernia containing Cecum, Sigmoid Flexure of Colon, or Urinary Bladder—Hernia in Tunica Vaginalis, or Congenital Hernia—Signs and Diagnosis—Complication with Undescended Testis—Treatment—Encysted Hernia in Tunica Vaginalis, or Infantile Hernia	783-793
FEMORAL HERNIA—Course—Relations—Contents—Signs—Diagnosis—Treatment—Operation	793-799
UMBILICAL HERNIA—In Children—In Adults—Treatment—Operation	800-802
VENTRAL HERNIA—Treatment	802-803
PELVIC HERNIA—Obturator—Symptoms—Treatment—Perineal—Vaginal—Pudendal—Scrotic	803-805
DIAPHRAGMATIC HERNIA—Congenital Defect of Diaphragm—Traumatic Diaphragmatic Hernia	805-807

CHAPTER LXIII.—INTESTINAL OBSTRUCTION.

ACUTE OBSTRUCTION—Causes—Symptoms—CHRONIC OBSTRUCTION—Symptoms—Intussusception—Symptoms—Diagnosis of Causes of Obstruction—Previous History—Mode of Invasion—General Condition of Patient—Character of Pain—Vomiting—Duration and Degree of Constipation—Physical Examination of Body, of Rectum—Quantity of Urine—TREATMENT—Acute Obstruction—Inversion of Patient—Puncture of Intestine—Operation—Treatment of Intussusception—Operation—Treatment of Chronic Obstruction—Gastrostomy—Colotomy—Littre's Operation—Amussat's Operation—Comparison of Littre's and Amussat's Operations	807-826
---	---------

CHAPTER LXIV.—TAPPING THE ABDOMEN.—OPERATIONS ON THE ABDOMINAL VISCERA.—TUMORS OF THE GROIN.

TAPPING THE ABDOMEN	826
REMOVAL OF PORTIONS OF THE INTESTINE	827-828
RESECTION OF THE PYLORUS	828-829

	PAGE
OPERATIONS ON THE LIVER—Abscess—Hydatids—Diseases of the Gall-bladder	829-831
EXTIRPATION OF THE SPLEEN	831
DISEASES OF THE UMBILICUS—Ulceration—Warty growth—Epithelioma—Umbilical Fistula	832
TUMORS OF THE GROIN—Varieties—Diagnosis—Pulsating—Non-pulsating—Reducible—Irrducible—Fluid Tumors—Solid Tumors—Treatment—Removal of Cystic or Solid Tumors	833-834

CHAPTER LXV.—DISEASES OF THE LARGE INTESTINE AND ANUS.

CONGENITAL MALFORMATIONS—Narrowing and Partial Closure of Anus—Complete Closure of Anus—Occlusion of Rectum above Anus by Membranous Septum—Complete Absence of Anus—Treatment—Closure of Anus with Absence of Rectum—Treatment—Perineal Incision—Iliac Incision—Lumbar Incision—Absence of Anus: Opening of Rectum into other Canals	834-837
STRICTURE: SIMPLE, SYPHILITIC, AND MALIGNANT—Simple or Fibrous—Symptoms—Progress—Treatment—Syphilitic Stricture of Large Intestine—Cancer and Malignant Stricture—Symptoms—Treatment—Cancer of Anus—Sarcomata of Rectum—Papillomata—Polypi	837-846
RECTAL FISTULA—Recto-vesical Fistula—Treatment—Entero-vaginal Fistula—Recto-vaginal Fistula—Treatment—Entero-vesical Fistula	846-849
ULCE AND FISSURE OF THE ANUS—Symptoms—Causes—Treatment—Spasmodic Contraction of Sphincter Ani—Treatment—Atony of Rectum—Treatment	849-851
ABSCESS AND FISTULA—Acute Ischio-rectal Abscess—Chronic Abscess—Treatment—Anal Abscess—Fistula in Ano—Extent—Varieties—Complete—Incomplete or Blind—Operation for Fistula in Ano	851-857
HÆMORRHOIDS OR PILES—Varieties—Predisposing Causes—Exciting Causes—Structure—External Hemorrhoids—Symptoms—Internal Piles—Longitudinal or Fleshy—Globular—Symptoms—Hemorrhage—Complications—Terminations—Subsidence—Coagulation—Suppuration—Sphacelus—Diagnosis—Of Hemorrhoidal Tumors—Of Hemorrhoidal Flux—Treatment—Constitutional—Local—Operation—Excision—Ligature—Smith's Operation—Galvanic Écraseur—Crushing—Caustics—Dangers attending Operations for Piles—Moist Condition of Skin around Anus—Pruritus Ani	857-870
PROLAPUS ANI—Causes—Diagnosis—Treatment—Palliative—Curative—Ligature—Prolapsus of the Rectum—Causes—Treatment—Protrusion of an Ovarian Cyst	870-874

CHAPTER LXVI.—SECONDARY DISEASES OF THE URINARY ORGANS ARISING FROM SURGICAL CAUSES.—PYÆMIA AND SEPTICÆMIA IN URINARY DISEASES.

MORBID CONDITIONS OF THE BLADDER—Diseased Conditions of the Ureters and Pelvis of the Kidney—MORBID CONDITIONS OF THE KIDNEYS—Results of Pressure—Acute Diffuse Interstitial Inflammation—Acute Interstitial Nephritis with Scattered Abscesses—Effects of Former Attacks from which the Patient has Recovered—Causes of Interstitial Inflammation—Tension—Reflex Irritation of Kidney—Septic Matter in Pelvis of Kidney—Symptoms of Kidney

	PAGE
Disease in Surgical Affections of Genito-urinary Organs—Urethral Fever or Uremic Fever—Prognosis—Treatment—Pyemia and Septicæmia in Diseases of the Urinary Organs	875-889

CHAPTER LXVII.—SURGICAL OPERATIONS ON THE KIDNEY.

STONE IN THE KIDNEY—Symptoms—Treatment—Calculous Pyelitis—Tubercular or Scrofulous Kidney—Symptoms—Pyonephrosis—Hydronephrosis—Treatment—Tumors—Carcinoma and Sarcoma—Diagnosis of Renal Tumors—Treatment of Carcinoma or Sarcoma—Fistulous Communications—Floating Kidney	889-895
OPERATIONS ON THE KIDNEY—Exploration—Aspiration—Nephro-lithotomy—Nephrotomy—Nephrectomy—Abdominal Nephrectomy—Results	895-899

CHAPTER LXVIII.—URINARY CALCULUS AND LITHOTOMY.

URINARY DEPOSITS AND CALCULI—Uric or Lithic Acid Deposits—Calculi—Treatment—Deposits of Oxalate of Lime—Calculi—Treatment—Phosphatic Deposits—Varieties of Phosphates—Calculi—Treatment—Cystine—Xanthine or Xanthic Oxide—Carbonate of Lime—Chemical Examination	899-905
STONE IN THE BLADDER—Structure of Calculi—Origin—Number—Spontaneous Fracture—Physical Characters—Size—Weight—Hardness—Shape—Position—Causes—Age—Sex—Geographical Distribution—Symptoms—Pain—Increased Frequency of Micturition—Stoppage of Flow of Urine—Stone in Elderly Men—Stone in Children—Encysted Calculus—Physical Diagnosis of Stone—Sounding Bladder—Errors in Sounding—Examination by Manipulation—Stone in Women—Pathological Changes induced by Calculus	905-916
LITHOTOMY—Instruments—Preparation of Patient—LATERAL OPERATION—Stages—Position of Knife—Incision of Prostate—Extraction of Stone—Lithotome for Lateral Lithotomy—After-treatment of Lithotomy—Lateral Lithotomy in Boys—Difficulties during Lithotomy—In Finding Stone—In Entering Bladder—In Seizing and Extracting Stone—From Position of Stone—From Fixture of Stone—From Fibroid Tumors in Prostate—From Rickets of Pelvic Bones—From Shape and Size of Stone—Removal of Large Stone—Incision of Right Side of Prostate—Crushing Calculus in Bladder—Difficulty from Fracture of Stone—Accidents during Lithotomy—Hemorrhage—Wound of Bulb—Missing the Urethra—Wound of Rectum—Wound of Posterior Part of Bladder—Difficulties in Children—Sources of Danger and causes of Death after Lithotomy—Statistics of Mortality—Influence of Age—of Shock—State of Kidneys—Prolonged Operation—Hemorrhage—Cystitis—Diffuse Inflammation of Areolar Tissue of Perineum—From Cutting beyond Prostate—From Bruising and Over-distension—Peritonitis—Sloughing—Pyæmia and Septicæmia—Other Methods of Performing Lithotomy—MEDIAN LITHOTOMY—History—Operation—Comparison between Median and Lateral Operations—General Ease and Simplicity—Hemorrhage—Wound of Bulb—Wound of Rectum—Treatment of Prostate—Manipulation of Forceps and Extraction of Stone—Indications for Median Operation—BILATERAL LITHOTOMY.—MIDIO-BILATERAL OPERATION.—RECTO-VESICAL LITHOTOMY.—HIGH OR SUPRAPUBIC OPERATION	916-955

CHAPTER LXIX.—URINARY CALCULUS (*continued*).

	PAGE
LITHOTRITY—History—Lithotritry as Practised before 1878—Instruments—Preparation of Patient—Anæsthetics—Operation—Introduction of Lithotrite—Seizure of Stone—Breaking Stone—Lithotritry subsequently to 1878—Bigelow's Operation—Accidents in Lithotritry—Impaction of Angular Fragments in Urethra—Chronic Enlargement of Prostate—Dangers in Lithotritry—Cystitis—Atony of Bladder—Disease of Kidneys—Constitutional Disturbance—Perineal Lithotritry—Results—Applicability	955-975
COMPARISON BETWEEN LITHOTOMY AND LITHOTRITY—Statistics—Circumstances determining Selection—Age—Size and Character of Stone—Conditions of Urinary Organs—Choice of Operation of Lithotomy—Result of Operations for Stone—Recurrence of Calculus after Operation—Treatment	975-988
URETHRAL CALCULUS—Symptoms—Treatment—Impaction of Calculus in Urethra of Boys	983-985
PROSTATIC CALCULUS—Characters—Symptoms—Treatment	985-986
CALCULUS IN THE FEMALE—Statistics—Symptoms—Removal—Lithectomy—Simple Dilatation—Dilatation with Incision—Lithotomy—Suprapubic—Urethral—Vaginal—Lithotritry in the Female	986-990

CHAPTER LXX.—DISEASES OF THE BLADDER.

CONGENITAL MALFORMATION—Extroversion—Treatment—Ayre's Operation—Wood's Operation	990-998
CYSTITIS—Acute—Termination—Treatment—Chronic Cystitis—Pathological Changes—Symptoms—Treatment—Irritable Bladder—Causes—Diagnosis—Treatment—Cystotomy—Irritable Bladder in Boys—In Women	998-1001
ATONY OF THE BLADDER—Retention of Urine—Symptoms—Diagnosis—Results—Treatment—Incontinence of Urine—Passive—Distention of Bladder with Overflow—Active Incontinence—Treatment—Hysterical Retention and Incontinence—Painful Conditions of the Bladder	1001-1007
TUBERCLE OF THE BLADDER	1007
SACCULE OF THE BLADDER	1007-1008
TUMORS OF THE BLADDER—Villous Tumor or Papilloma—Mucous Polypi in Children—Sarcoma—Symptoms—Diagnosis—Treatment—Cancer—Treatment	1008-1011
HEMATURIA—Sources—Kidneys—Bladder—Prostate—Urethra—Treatment	1011-1013

CHAPTER LXXI.—DISEASES OF THE PROSTATE.

PROSTATITIS—Symptoms—Treatment—Prostatic Abscess—Retention of Urine—Chronic Induration of the Prostate—Diagnosis—Treatment—Deep-seated and very Chronic Abscess	1013-1016
CHRONIC ENLARGEMENT OF THE PROSTATE—Characters—Simple Prostatic Tumors—Mechanical Effects on Urinary Organs—Moral Effects of Enlarged Prostate—Symptoms—Complete Retention of Urine—Diagnosis—Treatment—Prostatic Catheter—Treatment of Complete Retention—Puncture of Bladder above Pubes—Puncture through Rectum—Forcible Catheterism or Tunnelling the Prostate	1016-1026

OTHER DISEASES OF THE PROSTATE—Atrophy—Cancer—Tubercle—Cysts or Cavities	1026-1027
--	-----------

CHAPTER LXXII.—DISEASES OF THE URETHRA.

URETHRITIS—Symptoms—Treatment	1027-1028
GONORRHEA—Cause—Character—Symptoms—Incubative Stage—Acute or Inflammatory Stage—Chronic Stage—Gleet—Treatment of Gonorrhea—Treatment of Gleet—Complications—Inflammation of Lymphatics of Penis—Chordee—Acute and Chronic Prostatitis—Inflammation of Neck of Bladder—Cystitis—Pyelitis and Nephritis—Retention of Urine—Hemorrhage from Urethra—Urethral or Periurethral Abscess—Sequences of Gonorrhea—Warts—Stricture—Induration and Thickening—Gonorrheal Epididymitis—Conjunctivitis—Treatment—Scleritis—Treatment—Inflammation of Nose—Gonorrhea of Rectum—Rheumatism—Pyemia—Cutaneous Eruptions—Gonorrhea in the Female—Diagnosis—Treatment	1028-1042
STRICTURE OF THE URETHRA—Varieties—Spasmodic Stricture—Causes—Symptoms—Treatment—Congestive Stricture—Causes—Symptoms—Treatment—Organic Stricture—Age—Seat—Pathological Appearances—Amount of Constriction—Dilatation of Urethra behind Stricture—Chronic Cystitis in Bladder—Dilatation of Ureters—Symptoms—Local Signs—Examination of Patient for Stricture—Treatment—Gradual Mechanical Dilatation—Introduction of Catheters—Gum-elastic and Metal Instruments—Results of Introduction of Instruments—Accidents attending Catheterism—Nervous Symptoms, Rigors, and Urethral Fever—Treatment—Suppression of Urine—Hemorrhage—Inflammation—False Passages—Continuous Dilatation—Caustics—Forcible Expansion or Rupture—Sliding Tubes—Expansion by Screw Mechanism—By Wedge—Division of Stricture—Internal Urethrotomy—Results—External Urethrotomy—Operation for Permeable Stricture—Perineal Section—Result—Comparison of Methods of Treatment—Stricture of Urethral Orifices—Impermeable Strictures—Operations for Impermeable Stricture—Operation from Behind—Operation from Front—General Results of Treatment of Stricture	1042-1070
COMPLICATIONS AND RESULTS OF STRICTURE—Retention of Urine—Treatment—Forcible Catheterism—Opening Urethra behind and through Stricture—Puncture of Bladder through Rectum—Puncture above Pubes—Employment of Aspirator—Conditions requiring Puncture of Bladder—Extravasation of Urine—Local Effects—Constitutional Disturbance—Treatment—Perineal Abscess—Characters—Treatment—Urinary Fistula—Treatment—Urethroplasty—Stricture of Female Urethra	1070-1081
URINARY VAGINAL FISTULE—Varieties—Urethra-vaginal—Vesico-vaginal—Results—Treatment—Sim's and Bozeman's Operations	1081-1084
TUMORS IN THE URETHRA—Polypoid Tumor—Treatment—Excision—Ligature—Caustics—Cautery	1084-1085

CHAPTER LXXIII.—DISEASES OF THE PENIS AND SCROTUM.

DISEASES OF THE PENIS—Complete Arrest of Development of Male Sexual Organs—Congenital Malformation—Adhesion of Penis to Scrotum—Hypospadias—Treatment—Epispadias—Phimosis—Congenital—Acquired—Treatment—Operation—Dilatation of Phimosis—Slitting-up Prepuce—Circumcision for Con-
--

	PAGE
genital Phimosis in Infants—In Boys or Adults—Paraphimosis—Treatment— —Balanitis and Posthitis—Treatment—Herpes of Glans and Prepuce—Hyper- trophy of the Prepuce—Warts—Horny Excrescences—Persistent Priapism— Warts—Gangrene of Penis—Fibrous Tumor of Penis—Cancer of Penis— —Squamous Epithelioma—Causes—Diagnosis—Treatment—Amputation of Penis—Nævus and other Tumors	1085-1097
DISEASES OF THE SCROTUM—Inflammatory Edema—Treatment—Hypertrophy or Elephantiasis—Treatment—Epithelioma—Treatment	1097-1099

CHAPTER LXXIV.—DISEASES OF THE TESTIS AND CORD.

MALPOSITION OF THE TESTIS—Treatment	1099-1100
NEURALGIA OF THE TESTIS—Causes—Treatment	1100-1101
INFLAMMATION OF THE TESTIS—Orchitis and Epididymitis—Acute Inflammation —Seat—Symptoms—Atrophy of Testis—Subacute Orchitis—Treatment—Of Acutely Inflamed Testicle—Of Subacute Orchitis—Strapping the Testis— Abscess—Inflammation of Testis in Inguinal Canal—Inflammation and Abscess of Cord—Chronic Orchitis	1101-1104
HYDROCELE AND HÆMATOCELE—Hydrocele of Tunica Vaginalis—Congenital Hydrocele—Symptoms—Treatment—Tapping—Injection of Iodine—Seton— Antiseptic Method—Acupuncture—Encysted Hydrocele—Hydrocele of Cord —Diffused Hydrocele of Spermatic Cord—Hæmatocele—Characters—Symp- toms—Diagnosis—Treatment—Hæmatocele of Spermatic Cord—Diagnosis— Treatment	1105-1115
VARICOCELE—Causes—Symptoms—Diagnosis—Treatment—Radical Cure	1115-1119
SOLID ENLARGEMENTS OF TESTIS—Simple Sarcocoele—Structure—Treatment— Tubercular Testicle, Scrofulous Testicle, or Tubercular Sarcocoele—Symptoms —Structure—Prognosis—Treatment—Syphilitic Orchitis or Syphilitic Sarco- coele—Simple Inflammatory Form—Structure—Gummatous Form—Structure —Prognosis—Treatment—Diagnosis of Simple, Tubercular, and Syphilitic Sarcocoele—Cystic Disease or Cystic Sarcoma of Testis, or Cystic Sarcocoele— Diagnosis—Sarcoma of the Testicle—Enchondroma of Testicle—Cysts con- taining Colored Matters—Cancer of the Testicle, or Malignant Sarcocoele— Characters—Symptoms—Treatment—Structural Disease in Undescended Testis	1119-1129
OPERATION OF CASTRATION	1129-1131
GENERAL DIAGNOSIS OF SCROTAL TUMORS—Reducible Tumors—Irreducible Tumors	1131-1133
SPERMATORRHEA AND IMPOTENCE—Sexual Melancholia—True Spermatorrhœa Diagnosis—Treatment—Spasmodic Spermatorrhœa—Treatment—Impotence —Asperma—Sterility	1133-1137

CHAPTER LXXV.—DISEASES OF THE FEMALE GENITAL ORGANS.

INTRODUCTION OF INSTRUMENTS—Speculum Vaginæ—Female Catheter	1137-1138
DISEASES OF THE EXTERNAL ORGANS AND VAGINA—Hypertrophy of Labia— Condylomata or Verruæ—Cystic Tumors—Imperforate Vagina—Imperforate Hymen—Absence of Uterus and Ovaries—Hypertrophy of Clitoris—Removal of Clitoris—Vaginal Tumors—Vaginal Hemorrhoids—Prolapsus of Vagina— Rectocoele—Cystocoele—Vaginal Discharges—Treatment	1138-1142

TUMORS OF THE UTERUS —Subperitoneal, Intramural, and Submucous Growths —Polypi—Malignant Affections: Glandular Carcinoma—Epithelioma (Cauliflower Excrescence)—Sarcoma	1142-1144
TUMORS OF THE OVARY —Diagnosis—Treatment—Medical Means—Tapping— Incision and Drainage—Other Means—Ovariectomy—Statistics—Preparation of Patient—Operation—After-treatment.— HERNIA OF THE OVARY	1144-1153

APPENDIX.

CORROSIVE SUBLIMATE AS AN ANTISEPTIC	1155-1157
INDEX TO VOLUME II.	1159

LIST OF ILLUSTRATIONS IN VOL. II.

FIG.	PAGE	FIG.	PAGE
415 Syphilitic Onychia	81	446 Posterior Tibial Nerve Flattened by Pressure of Aneurism	181
416 Hypertrophy of Toe-nail	85	447 Aneurism of Calf Undergoing Spontaneous Cure	185
417 Rodent Ulcer of Back of Hand	40	448 Aortic Aneurism opening into Esophagus	189
418 Rodent Ulcer, Perforating Skull	40	449 Stellate Rupture of Aortic Aneurism into Pericardium	189
419 Rodent Ulcer, Section of (Warren)	42	450 Diagram of Anel's Operation	142
420 Cancerous Ulcer of Leg	44	451 Diagram of Hunter's Operation	142
421 Neuroma, with nerve-filament spread over it	59	452 Diagram of the Distal Operation	142
422 West Indian Elephantiasis	71	453 Femoral Artery tied for Aneurism; laid open from Seat of Ligature to Sac	145
423 Lymphadenoma at Root of Neck	77	454 Popliteal Aneurism Compressing Vein: Gangrene of Limb	164
424 Harelip Pins applied to Varicose Veins	91	455 Sac laid open: Cured by Compression	156
425 Syringe for Injecting Nævus	96	456 Sac of Tubular Aneurism, Cured by Compression	157
426 Ligature of a Nævus: mode of using needles	98	457 Carte's Compressor for Middle of Thigh	158
427 Diagram of Nævus tied	98	458 Carte's Compressor for Groin	158
428 Diagram of Ligature of Flat and Elongated Nævus	99	459 Two Compressors Applied	158
429 Diagram of Flat and Elongated Nævus tied	99	460 P. H. Watson's Weight Compressor	159
430 Nævus of Lower Lip: Front view	101	461 Tuffnell's Compressor	160
431 Nævus of Lower Lip: Side view	102	462 Tuffnell's Compressor Applied	160
432 Large Nævus of Upper Lip: Front view	102	463 Erosion of Intervertebral Substance by a Small Aneurism	174
433 Large Nævus of Upper Lip: Side view	102	464 Aneurism of Descending Aorta, Eroding, and Traversing Vertebrae	174
434 Nævus of Tongue	103	465 Aneurism of Arch of Aorta, bursting into Left Bronchus	175
435 Atheromatous Material under Microscope	112	466 Aneurism of Innominate, Stretching Recurrent Laryngeal and Displacing Trachea	182
436 Atheroma of Aorta: Section	112	467 Diagram of Treatment of Innominate Aneurism by Ligature of Subclavian	184
437 Annular Calcification of Artery	117	468 Diagram of Treatment of Innominate Aneurism by Ligature of Carotid	184
438 Tubular Calcification of Artery	117	469 Diagram of Treatment of Innominate Aneurism by Ligature of Subclavian and Carotid	184
439 Thrombosis of Two Large Branches of Abdominal Aorta	120	470 Aneurism of Arch of Aorta, Simulating Carotid Aneurism	189
440 Embolism of Axillary Artery with Secondary Thrombosis	120	471 Incision for Ligature of Carotid	193
441 Large Fusiform Aneurism of Ascending Aorta, bursting into Pericardium	125		
442 Sacculated Aneurism of Ascending Aorta	126		
443 Aorta laid open, showing Mouth of Sacculated Aneurism	126		
444 Dissecting Aneurism of Aorta	128		
445 Large Aneurism of Ascending Aorta, Projecting against ribs	130		

FIG.	PAGE	FIG.	PAGE
472 Anatomy of Right Carotid at Seat of Ligature . . .	198	505 Central Necrosis: New Bone, Clones, and Included Sequestrum . . .	304
473 Fusiform Aneurism of Basilar . . .	202	506 Reproduction of Lower Jaw after Phosphorus-necrosis . . .	804
474 Aneurism of Left Internal Carotid bursting into Lateral Ventricle . . .	205	507 Acute Necrosis of Tibia: Deficient Formation of New Bone . . .	805
475 Aneurism of Left Internal Carotid, seen from below . . .	205	508 Cutting Pliers for Removing Necrosed Bone . . .	807
476 Ligature of First Part of Subclavian . . .	218	509 Cutting Pliers for Removing Necrosed Bone . . .	807
477 Ligature of Subclavian and Carotid for Subclavian Aneurism . . .	218	510 Cutting Pliers for Removing Necrosed Bone . . .	807
478 Ligature of Third Part of Subclavian . . .	225	511 Gouge Forceps . . .	807
479 Anatomy of Third Part of Subclavian . . .	225	512 Straight Saw . . .	807
480 Anatomy of Third Part of Subclavian . . .	225	513 Necrosis Forceps . . .	807
481 Anatomy of First Part of Axillary . . .	235	514 Bone Forceps . . .	806
482 Anatomy of Third Part of Axillary . . .	235	515 Cells from Spindle-celled Sarcoma of Scapula . . .	322
483 Incision for Ligature of Brachial at Middle of Arm . . .	238	516 Ossifying Spindle-celled Sarcoma of Scapula Section . . .	322
484 Anatomy of Brachial at Middle of Arm . . .	238	517 Cells from Second Recurrence of above . . .	322
485 Anatomy of Ulnar at Wrist . . .	239	518 Myeloid Cells from Tumor of Lower End of Femur . . .	323
486 Incisions for Ligature of Brachial at Bend of Elbow, and Radial and Ulnar at Middle of Forearm and at Wrist . . .	238	519 Fusiform and Out-shaped Cells from Myeloid Tumor . . .	323
487 Anatomy of Radial at Middle of Forearm . . .	239	520 Secondary Nodule of Calcified Sarcoma in Lung Section . . .	324
488 Ligature of External Ilac; Abernethy's Operation . . .	249	521 "Expansion" of Lower End of Femur by Sarcoma . . .	324
489 Femoral Vein Obliterated by Inguinal Aneurism . . .	256	522 Myeloid Tumor of Lower Jaw Invading Bone Section . . .	324
490 False Aneurism of Perforating Artery . . .	259	523 Peripheral Spindle-celled Sarcoma of Shaft of Femur . . .	325
491 Ligature of Superficial Femoral . . .	260	524 Peripheral Spindle-celled Sarcoma of Shaft of Femur Amputation at Hip success 1 . . .	325
492 Anatomy of Superficial Femoral in Scarpa's Triangle . . .	264	525 Malignant Growth of Head of Humerus . . .	326
493 Anatomy of Femoral in Hunter's Canal . . .	264	526 Microscopic Section through above growth . . .	326
494 Anatomy of Popliteal Artery . . .	2	527 Anæsthesia by Anastomosis of Parietal Bone . . .	330
495 Anatomy of Posterior Tibial Artery . . .	269	528 Interior of Knee destroyed by Acute Pyemic Arthritis . . .	341
496 Diffuse Osteomyelitis of Humerus . . .	279	529 Caries of Head of Tibia . . .	343
497 Carious Bone from Scrofulous (Osteitis of Skull) . . .	281	530 Rheumatoid Arthritis of Hip: Patient . . .	356
498 Scrofulous Vessels in Head of Tibia . . .	281	531 Section of Hip affected by Rheumatoid Arthritis . . .	357
499 Chronic Rarefactive Osteitis of Cancellous Tissue of Head of Tibia . . .	281	532 Osseous Ankylosis of Hip . . .	359
500 Abscess in Head of Tibia . . .	286	533 Butcher's Saw . . .	371
501 Bone Trephine . . .	288	534 Excision of Shoulder: Longitudinal Incision . . .	375
502 Section of Tibia: Chronic Osteitis and Circumscribed Abscess . . .	288	535 Shoulder Stump after Amputation by Spencer's Method . . .	375
503 Savary's Vertebrotome Probe . . .	297	536 Excision of Shoulder: Elliptical Incision . . .	376
504 Marshall's Osteotome . . .	299	537 Excision of Elbow: Sawing Lower End of Humerus . . .	381
		538 Excision of Elbow: T-shaped Incision . . .	384
		539 Excision of Elbow: T-shaped Incision: Bones Exposed . . .	384

LIST OF ILLUSTRATIONS.

xxiii

FIG.	PAGE	FIG.	PAGE
540	Excision of Elbow: Longitudinal Incision	579	Position assumed by Limb on forcibly distending Hip with Fluid (Barker)
541	Arm after Excision of Elbow	580	Bones from Acute Disease of Hip-joint in Adult
542	Arm after Removal of Radius	581	Patient with Chronic Hip Disease and Sinuses
543	Radius Removed	582	Head of Femur after Excision, from above case
544	Diagram of Bones of Wrist (Lister)	583	Apparatus for Extension by Weight in Hip Disease
545	Diagram of Tendons about Wrist (Lister)	584	Thomas's Hip-splint
546	Lister's Splint for Excision of Wrist	585	Thomas's Hip-splint applied
547	Hand after Excision of Wrist fixed on Lister's Splint	586	Sayre's Extending Apparatus for Hip-joint Disease
548	Thomas's Knee-splint	587	Acetabulum perforated in Hip Disease
549	Thomas's Knee-splint applied	588	Head of Femur Carious: from same case
550	Excision of Knee by Elliptical Incision	589	Patient, Three years after Excision of Head of Femur and much of Hip-bone
551	Application of Butcher's Saw to Head of Tibia	590	Excision in Femoral Coxaalgia
552	Portions of Femur and Tibia removed in Excision of Knee	591	Gowan's Osteotome applied to Femur
553	Portions of Femur and Tibia removed in Excision of Knee	592	Splint for use after Excision of Hip
554	Limb with Necrosis of Fibula	593	Incision Exposing Great Trochanter for Removal of Diseased Bone
555	Limb after Removal of Fibula	594	Patient with Rectangular Ankylosis of Hip: Spine straight
556	Diagram of Synovial Membranes of Foot	595	Same Patient: showing Curve of Spine allowing toes to touch ground
557	Foot with Disease of Os Calcis, Cuboid, and Calcaneo-Cuboid Joint	596	Lines of Section of Femur in Sayre's Operation for Ankylosis of Hip
558	Excision of Os Calcis	597	Application of Chain-saw in Sayre's Operation
559	Disease of Os Calcis: Foot before and after Operation	598	Saw used in Adams's Operation for Ankylosis of Hip
560	Disease of Astragalus	599	Application of Adams's Saw to Neck of Femur
561	Limb after Excision of Ankle-joint	600	Cross-legged Deformity (Lucas's case)
562	Excision of Astragalus: Foot before and after Operation	601	Enlarged Bursa over Olecranon
563	Disease of Cuneiform Bones	602	Toes Distorted by Pressure: Bunion
564	Large Spina Bifida	603	Apparatus for above Deformity
565	Angular Curvature of Dorsal Spine	604	Fibro-sarcoma of Sartorius
566	Caries of Lumbar Spine: no repair	605	Back View of and Section through above Tumor
567	Diagrams of Natural Curves of Spine	606	Back View of and Section through above Tumor
568	Change of Curve in Early Angular Curvature	607	Malignant Tumor in Sole
569	Change of Curve in Advanced Angular Curvature	608	Section through above Tumor
570	Attitude of Child in Advanced Angular Curvature	609	Lateral Curvature and Rotation of Spine
571	Support in Spinal Caries	610	Outline of Double Lateral Curve
572	Taylor's Spinal Support	611	Outline of Quadruple Curve
573	Application of Sayre's Plaster Jacket	612	Outline of Kyphosis
574	Sayre's Jacket Applied	613	Outline of Lordosis
575	Sayre's Jacket with Jury-mast		
576	Early Sacro-iliac Disease—Sacro-iliac		
577	Early Sacro-iliac Disease—Ilium		
578	Advanced Sacro-iliac Disease		

FIG.	PAGE	FIG.	PAGE
614 Patient with Lateral Curvature	492	655 Nasal Speculum	539
615 Support for Lateral Curvature	494	656 Nasal Speculum (Fränzel's)	539
616 Support for Posterior Excurvation	495	657 Bellows's Sound	544
617 Support for Posterior Incurvation	495	658 Diagram of Plugging Nostril by means of Bellows's Sound	544
618 Tenotomy-knife	498	659 Nasoorbital Tumor	549
619 Tenotomy-knife	498	660 Section of Epithelioma of Face	553

SCIENCE AND ART OF SURGERY.

DIVISION FOURTH.

DISEASES OF TISSUES.

CHAPTER XXXVII.

SURGICAL DISEASES OF THE SKIN AND ITS APPENDAGES.

THE various specific cutaneous affections, such as eczema, scabies, impetigo, acne, lepra, psoriasis, etc., probably fall within the province of the Surgeon, and are commonly treated by him in practice; but, as the consideration of these diseases would necessarily lead into the whole subject of Dermatology, the limits of this work would not allow me to discuss so extensive and special a branch of Surgery; and I must therefore content myself with the consideration of some of those affections of the skin, which, requiring manual assistance, may perhaps be more properly looked upon as within the scope of the present Treatise. These diseases may be considered under the several heads of Diseases of the Skin itself, including the various forms of non-malignant ulceration, and the malignant ulcers and tumors, and Diseases of the Appendages of the Skin, as the nails. We have already in Chapter VI. considered the ordinary non-malignant ulcers of the skin, and in Chapter XXXIV. some of the simple tumors that occur in connection with the tissues; we shall here, therefore, consider only the Diseases of the Appendages of the Skin and the Malignant Ulcers and Tumors.

DISEASES OF THE APPENDAGES OF THE SKIN.

DISEASES OF THE NAILS.—The nails may become diseased, as the result of mechanical injury, or as a part of some general cutaneous affection; they may suffer from inflammation of the matrix, or may grow into the soft tissue of the toes.

A violent blow or pinch often partly loosens the nail and causes an extravasation of blood beneath it. It then becomes black in color and slowly separates. No treatment is required beyond protecting the injured part by some convenient covering.

In some broken states of health, and especially in persons suffering from squamous disease of the skin, the nails occasionally become blackish or dark-brown in color, are rugged, dry, and cracked, scaling off, as it were, without any apparent affection of the matrix. This condition, of which I have seen several instances, is best cured by a course of alteratives or tonics, the disease yielding as the general health becomes improved. Arsenic will often be found of great service, either alone or with mercury.

Onychia is a disease of the nails dependent on inflammation of the matrix; it occurs under two forms, the *simple* and the *specific*.

In **Simple Onychia** there are redness, heat, and swelling, usually on one side of the nail, and in the angle of the tissue in which it is implanted, there is discharge of pus, and the nail gradually loosens, becomes dark colored, somewhat shrivelled, and may eventually be thrown off, a new nail making its appearance below, which commonly assumes a somewhat thickened and rugged shape. This disease usually results from slight degrees of violence, as the running of thorns and splinters into the fingers.

The treatment consists in cutting away any part of the nail that becomes loose, so that no discharges may accumulate beneath it. The inflammation may be subdued by hot moist applications. In some cases a lotion composed of liq. plumb. subacetatis ℥ss, rectified spirit ℥j, and water to one pint, will be found most efficacious.

Syphilitic Onychia is a more serious affection, and is often dependent on injuries inflicted on the finger during constitutional syphilis. In it a dusky-red or livid inflammation takes place at the sides or root of the nail, ulceration is set up, accompanied by the discharge of sanious and very fetid pus; and large loose granulations spring up at its root and sides, so that the end of the toe or finger that is affected (and this is most commonly either the great toe, the thumb, or the index finger) becomes greatly enlarged and bulbous in shape. The nail then shrivels, becomes brown or black, and peels off in strips (Fig. 415); after its separation, thick epidermic masses, forming

Fig. 415—Syphilitic Onychia.

abortive attempts at the production of a new nail, may develop at the base and sides. In the *Treatment*, both local and constitutional means are required. The first and most essential point is to *remove the nail*, either in whole or part, for it acts as a foreign body, and prevents the healing of the surface from which it springs; the ulcer may then be treated with iodoform or well rubbed with the nitrate of silver, and dressed with black

wash. Colles recommends fumigating it with a mercurial candle, made by melting a drachm of cinnabar and two ounces of white wax together. The constitutional treatment is that of syphilis. Sir A. Cooper recommends calomel and opium, but I have generally found bichloride of mercury, with sarsaparilla or cinchona, the most useful remedy.

Ingrowing of the Nail is an extremely painful and troublesome affection, principally occurring in the great toe, and brought about by wearing pointed shoes, by which the sides of the soft part of the toe are pressed upon, and made to overlap the edge of the nail. An ulcer here forms, the liability to which is greatly increased by the nail being cut square, so that the flesh presses against a sharp and projecting corner of it; this ulcer secretes a fetid sanious discharge, and large granulations are thrown up by it. The consequence is inability to walk or even stand with comfort.

Treatment.—In the very early stages before ulceration has taken place, further trouble may often be prevented by scraping the nail down along its middle with a piece of broken glass or a knife, till it is about as thin as a sheet of note paper. At the same time, its free end should be cut short in the middle, and its corners allowed to grow well beyond the matrix, so that the natural edge of the nail, and not a sharp angle, shall be in contact with the soft parts. When the soft parts begin to overlap the nail various plans have been devised with a view of raising the edge of the nail, and pressing aside the soft structures. I have never, however, seen much permanent benefit

result from any of these means; and the only method that is, I think, really serviceable to the patient, is the removal of the whole nail. As this operation is an excessively painful one, the patient should be anesthetized with nitrous oxide, or the matrix should be rendered insensitive by the ether-spray. The Surgeon holds the diseased toe in his left hand, and then, running one blade of a strong, sharp-pointed pair of scissors under the nail up to its very root, he cuts through its whole length, and, removing the scissors, seizes first one half and then the other with a pair of dissecting forceps, and twists them away from their attachments. The surface left is still covered by the deeper layer of the epithelium, and becomes covered with a dry layer of cuticle in a few days. The back of the scissors usually wounds the matrix in the middle line, and here granulations may form. The new nail grows straight and healthy. In some rare cases, however, I have seen a faulty direction assumed by it. If this should happen the nail must be again removed, and the matrix dissected away. Avulsion of the toe-nail is usually unattended by danger. I was, however, once called upon to amputate a foot for gangrene, which had followed the operation performed on an elderly person.

Fig. 416.—Hypertrophy and Deformity of Toe-nail.

HYPERTROPHY OF TOE-NAIL.—Occasionally from neglect the toe-nail may become enormously hypertrophied and twisted, looking more like a horn than a nail, as in the accompanying drawing (Fig. 416), taken from a patient in whom the nail had been allowed to grow uncut for twenty years, producing complete lameness. I removed the nail whole by avulsion, and a sound and useful foot resulted.

DISEASES OF THE SKIN.

LUPUS.—Under the term *lupus* various affections of the skin were formerly included, having but little in common with each other beyond running a chronic course and leading to destruction of the cutaneous tissues, with or without ulceration. It is now limited to two diseases which, although included under the common name, are in reality quite distinct. These two affections are distinguished as *Lupus Erythematosus* and *Lupus Vulgaris*. When the term *lupus* is used alone it is applied only to the latter disease.

Lupus Erythematosus.—This disease was originally described as a disease of the sebaceous follicles. Hebra, in 1845, gave it the name of *Seborrhœa Congestiva*. It is now generally known by the name of *Lupus Erythematosus*. It consists essentially in a chronic inflammation, affecting chiefly the sebaceous follicles and the tissues immediately surrounding them. There is an increased secretion of sebaceous matter from the follicle by which the acini of the gland become dilated and the duct widened. The parts immediately surrounding the follicle show the ordinary signs of chronic inflammation, the capillaries being dilated and the tissues infiltrated with small round cells. The disease terminates in destruction of the follicles, and the chronic inflammatory products partly degenerate and are absorbed, and partly become developed into cicatricial tissue.

The disease commences as a sharply defined red patch, the color of which disappears almost entirely on pressure. The redness is most marked round the orifices of the follicles. The spots may be isolated or in groups, and vary in size from a pin's head to a split-pea. The patch soon becomes covered by an adherent scale, which is greasy to the touch. If this be removed, it is found to be continuous with the plugs of altered sebaceous matter filling the

dilated ducts of the follicles. The patches itch slightly, but are not actually painful. As the disease advances the spots slowly increase in size at the circumference, while the central parts become paler, slightly depressed, and cicatricial—the thin scar-tissue being dry like parchment and often scaly. There is no tendency to suppuration or ulceration. Another and less common variety of the disease is described, in which it commences as numerous discrete spots, and spreads by the appearance of fresh patches, rather than by extension from a single centre. *Lupus erythematosus* is most common on the cheeks. It may occur also on the ears, lips, scalp, and the backs of the hands. The disease runs an extremely chronic course, often lasting many years, and causing great disfigurement. It has a great tendency to relapse after apparent cure. Attacks of erysipelas are not uncommon during its progress. The cause is unknown. No distinct connection has been traced between it and scrofula or syphilis, and it is not hereditary nor contagious. It commences usually in young adult life after the eighteenth year, and is most common in women.

Treatment.—No drug exerts any specific influence on the disease, and the constitutional treatment consists therefore merely in attending to the general health on ordinary principles. Locally, Kaposi states that he has found the application of *Emplastrum Hydrargeri* the most efficient mode of treatment. The surface may be cleaned before its application by being smeared with oil and well washed with soft soap. The plaster should be spread thickly on thin linen, and changed daily. Strong caustics are not to be recommended, and the results obtained by the application of superficial escharotics have not been very encouraging. Painting with iodine also has been recommended. It excites a certain degree of inflammation after a few applications, in consequence of which the sebaceous plugs in the ducts of the follicles seem to become softened and discharged, thus causing temporary improvement.

Lupus Vulgaris or Lupus: Pathological Appearances.—This disease commences in the deep layer of the cutis vera. In its earliest stage circular accumulations of small round cells are seen displacing the bundles of fibrous tissue. The surrounding vessels are dilated, and new capillaries exist amongst the cells, and thus the nodule resembles in structure ordinary granulation-tissue. These circular masses of cells gradually increase in size, and by their pressure destroy the tissue of the true skin and thus approach the surface, until at last the papillary layer is implicated and the new growth is covered merely by the epithelium. During this process neighboring groups of cells coalesce, and processes of cell infiltration extend along the vessels and surround the hair bulbs and follicles, so that in its fully developed stage a lupoid tubercle consists of an infiltration, and more or less complete destruction, of the normal tissue of the skin from the papillae to the subcutaneous fat. On examining a section of a fully developed patch, non-vascular nodules composed of a giant cell, surrounded by larger "epithelioid" cells, and again by ordinary lymphoid or small round cells, will always be met with. These are identical in appearance with the nodules of gray granulations, a fact which has led some pathologists to regard lupus as a local tuberculosis of the skin; but this view is not generally accepted.

After a patch of lupus has reached its full development, retrogressive changes take place. These may be of two kinds. In the first, some of the cells may become cloudy from fatty degeneration, break up, and be absorbed, while a development of cicatricial fibrous tissue takes place from the remainder. Thus the process comes to an end without ulceration, and although the epithelial covering has been throughout intact, a scar results similar in appearance to that caused by a superficial burn. When the disease takes course, it is described as *non-ulcerative lupus*, *lupus non-exedens*, or *lupus*

exfoliatus (Kaposi). In the second form the fatty degeneration affects the whole of the cellular mass, which then softens, the cuticle covering it is thrown off, and the disintegrated caseous mass is discharged, leaving an ulcer which may slowly extend. The disease is then known as *ulcerative lupus*, *lupus exedens*, or *lupus exulcerans*. These two forms are therefore mere modifications of one process; the fate of the new growth, whether it is absorbed without ulceration or whether it softens and is discharged, being due to accidental, local, or constitutional conditions, the nature of which cannot in all cases be determined.

Symptoms.—Lupus commences in the form of tubercles, buried in the skin. They are separate from each other, and arranged in groups, or sometimes in irregular circles. At first they form red or reddish-brown patches, from a line to a quarter of an inch in diameter, which are not raised above the surface. The tubercles continue slowly to develop, till after some weeks they become slightly elevated, and covered by a fine branny epidermic desquamation. Several patches may coalesce, forming larger tubercles, and at the same time new patches appear, so that all stages of development may be observed at once in the same case. At this point the two forms of the disease diverge. In *Lupus non-exedens*, the tubercle becomes paler in color and gradually shrinks and disappears. The integument which has been affected by the disease may be in one of two states; it may either continue red, irritable, and branny, having the appearance of a thin cicatricial tissue, and in this way the greater part of the whole of the face may be affected; or it may leave a firm, white, smooth, and depressed cicatrix, exactly resembling that produced by a burn, along the margin of which the disease slowly spreads, in the form of an elevated ridge composed of soft bluish-white or reddish tubercles.

In *lupus exedens*, instead of disappearing, the tubercles become pale in color and softened; the epithelial covering separates, and the disintegrated cheesy mass mixed with some pus is discharged, and drying on the surface forms a scab. This process may be accompanied by considerable inflammation of the skin surrounding the lupoid patches, with heat, swelling, and pain. When the scab separates, an ulcer is seen beneath. It is sharply defined, with slightly raised edges, and usually a smooth red surface which bleeds readily. This sore may gradually extend both superficially and in depth, and when seated on the nose often leads to destruction of the alæ and columella. *Lupus vulgaris* seldom, however, spreads very deeply, although large areas of skin may be affected, and the most frightful deformity result.

Situation.—Lupus may occur on any part of the body, but it is far more commonly met with in the face than elsewhere. The nose and cheeks are the parts of the face usually attacked. It may commence on mucous membranes, but most commonly reaches them by extension from the skin. It is, however, occasionally met with as a primary disease in the pharynx and larynx. It then usually assumes the ulcerative form, and may lead to extensive destruction of the mucous membrane.

Sex and Age.—*Lupus vulgaris* occurs almost with equal frequency in the two sexes. It begins most commonly in early life, "rarely before the third year and almost never after puberty" (Kaposi).

Complications.—Beyond the deformity caused by the contraction of the scars, the disease itself causes no serious consequences. As a rule, it in no way affects the general health. Erysipelas not uncommonly attacks the diseased surface, and cases have been recorded in which epithelioma has arisen from the scars.

Causes.—Until recently it was universally assumed that lupus owed its origin to a scrofulous taint in the constitution, and possibly sometimes to

inherited syphilis; but at the present time most authorities are agreed that although both these views may be true of some cases, yet in the great majority no evidence is forthcoming to justify them. The disease is not hereditary and is not communicable.

Prognosis.—Lupus is characterized by its slow course, and its tendency to relapse after apparent arrest; it is, however, never directly fatal.

Diagnosis. The diagnosis is not always easy, the disease being especially apt to be confounded with some forms of impetigo, with tertiary syphilitic ulcerations, with rodent ulcer, and with cancer. From *impetigo* it may be distinguished by the absence of pustules, and of the thick gummy crusts characteristic of that affection, as well as by the less extent of surface implicated. From *tertiary syphilitic ulcerations*, especially from softening cutaneous gummata, it is often very difficult to distinguish it. The history of the disease, the age of the patient at the time of invasion, and the more rapid progress of the syphilitic affection will usually enable the Surgeon to make a correct diagnosis. From *squamous epithelioma*, it is usually distinguished with ease; in lupus the tubercles are numerous, and there are many centres of ulceration, the glands are seldom enlarged, and the disease commences in early life; in cancer the primary disease is single, the glands are early affected, the disease commences after middle life. In lupus the ulcer is flat, with sharply cut edges; in cancer it is rugged and irregular, with hard, elevated, and everted edges. The diagnosis from *rodent ulcer* will be given with that disease.

Treatment.—The *constitutional treatment* of lupus was formerly considered of much importance. Cod-liver oil, the iodides of potassium, mercury, and arsenic, either alone or combined with various other drugs, have been credited with a curative, or at least a beneficial influence on the disease. At the present time when, by more extended clinical observation, simple scrofulous sores and tertiary syphilitic ulcerations have been clearly distinguished from true lupus, the efficacy of drugs in the treatment of the disease has been found to be much less than was once supposed. Kaposi states that no drug exerts any definite specific influence on the progress of the disease. Still, as lupus frequently occurs in patients who are in feeble health, anæmic or scrofulous, constitutional treatment must on no account be neglected; for, although drugs may exert no specific influence, it is evident that by improving the general health they will promote the healing of the ulcers and so tend to diminish the severity of the disease. The diet should be carefully regulated and nutritious, and general hygienic conditions must be attended to.

It is on the *local treatment* that we have chiefly to rely, and the only efficient means are those by which the morbid growth is completely destroyed. In the milder form, non-ulcerative lupus, or lupus non-exedens, an attempt may however be made to arrest the disease without actual destruction of the growth. For this purpose mercurial plaster, painting with tincture of iodine, or with a strong solution of nitrate of silver, and the application of zinc or carbonate of lead ointment have been sometimes found efficacious. Lotions containing glycerine are especially useful as they prevent the surface from becoming dry and harsh. If the disease be situated on the face, care must be taken to avoid exposure to cold winds, dust, etc. Volkmann recommends *punctatum* scarification by means of an instrument composed of several small blades set closely together. The object of this treatment is to obliterate the vessels and thus arrest the growth and promote absorption of the morbid products. Should these methods fail, the only hope of arrest consists in the destruction of the diseased tissue. If it be limited in extent, the patch may be removed by the use of the cautery, and frequently the cicatrix becomes prominent and irregular

from a fibroid growth resembling keloid. In lupus exedens destruction of the growth is the only treatment which holds out any prospect of success. In doing this the means adopted must be efficient. Feeble caustics only irritate the parts and aggravate the disease. The growth may be completely removed by excision, by scraping, by caustics, and by the actual cautery.

Excision is applicable only to small isolated patches, and is seldom practicable. Scraping has lately been found of great service. It is done by means of "sharp spoons" (Fig. 95, p. 258, vol. i.). The brittle tissue of the growth is easily removed, and the sensation given by the denser healthy tissues beneath shows when the operation has been carried far enough. The bleeding is very free, but is easily arrested by pressure with dry cotton-wool. It is wiser to apply some caustic to the scraped surface to insure the complete destruction of the growth. The caustics that have been used are various; solid nitrate of silver, chloride of zinc, acid nitrate of mercury, and fuming nitric acid have all been recommended, and are equally efficient. The actual cautery is easily controlled, and can often be used when other caustics are inapplicable. In most cases Paquelin's thermo-cautery is the best, but in deep cavities, as the mouth or nose, the galvanic cautery is more easily applied.

If when the case comes under observation there is considerable inflammation round the patch, it is better to subdue this by warm moist applications before adopting any of the above modes of treatment.

After the growth has been destroyed healthy granulations spring up, and the sore must be treated on ordinary principles. Vaseline and iodoform ointment often seems to promote the healthy healing of the raw surface.

However successful the treatment may appear at first, relapses are very common, but in a large number of cases as life advances the disease seems to become less acute, and finally ceases to reappear. The cicatrix that forms after lupus is healed in thin, and readily breaks down, giving way on exposure to cold, or on the occurrence of constitutional derangement. The patient should therefore, for some length of time after recovery, be careful not to expose himself to any such influences. The scars often lead to great deformity, drawing down the eyelids, distorting the mouth, and sometimes closing the nostrils. Various plastic operations are sometimes required to remedy these defects.

RODENT ULCER, NOLI-ME-TANGERE, or CANCROID, was formerly included under lupus exedens. It is one of those remarkable affections that stand midway between simple and malignant diseases; being, so far as constitutional causes or secondary complications are concerned, apparently of a simple nature, while, to a certain extent, in regard to structural condition and entirely in respect to local effects, it is of a malignant character. The disease consists essentially of a malignant growth of very feeble vitality and slight activity of development. This invades the surrounding structures and destroys them, and in its turn breaks down, disintegrates, and is thrown off, thus causing a progressive destruction of tissue. The disease is especially characterized by its slow progress, by its eroding nature, and by the impossibility of healing it by all ordinary methods of treatment. It is essentially a disease of advanced age, seldom beginning before 45 or 50. Its duration is in any given case indefinite; seldom less than five or six years, occasionally extending to twenty or thirty. It affects individuals of either sex indiscriminately; and usually occurs in persons who are otherwise perfectly healthy. The health also is not influenced materially, if at all, by its long duration. I have seen persons, who have been victims to it for more than twenty years, in apparently robust health. But it is eventually and inevitably fatal, unless removed by operation.

It always commences in the skin, usually on healthy integument; but occasionally it primarily affects a part which is the seat of some chronic change of structure, as a mole, a wart, or a scar. It

Fig. 417. — Rodent Ulcer of Back of Hand. Amputation.

may affect any part of the head, face, or extremities. The face is its seat of election, especially in the upper parts, such as the forehead, the side of the nose, the inner angle of the eye, or the temple. It spreads slowly by continuity of tissue, never by disseminated local or by secondary deposits. It may invade all tissues; the skin primarily, the cartilage of the ear, the alae and septum of the nose, the parotid gland, the conjunctiva, and the eyeball. It is especially destructive to bone when once it attacks it. It erodes and eats away the bone, without caries or necrosis. It may penetrate to the dura mater, and invade the brain. It progresses, however, by preference superficially, not in depth; hence it is seldom attended by hemorrhage even in the more advanced stages. The neighboring lymphatic glands do not become implicated, and secondary visceral deposits are never met with. As the ulceration extends, there is often a tendency to imper-

fect cicatrization on one margin, whilst the disease is making progress at the other.

Symptoms. — In whatever situation it begins, its first appearance is in the shape of a tubercle or hard pimple of a brownish-red color. This tubercle ulcerates slowly; and then the disease extends. Moore, to whom we are indebted for a most lucid account of this terrible affection, lays especial stress on its commencement in a hard wart, and its continued extension by a hard margin. This ulcerated tubercle becomes covered by a scab; but, as the process of destructive ulceration progresses the sore becomes too large to be covered in this way, and an ulcer is left. This ulcer, which constitutes

the disease and is the true "*Lupus*," or "*Noli-me-tangere*," of the older authors, presents the following characters. It is always single, and spreads solely by continuity of tissue. It is depressed slightly below the surface, is of a pale pink color, with a furrowed rather than a granulating surface, resembling by its furrowed smoothness an irregular layer of pink wax, and is usually painless, except where cicatrizing. Its edges are slightly raised, the degree varying in different cases and depending on the closeness with which the destruction of the new growth follows its development. In some cases the two follow each other so closely that the ulcer appears to be a simple loss of tissue, scarcely any thickening of the edge being recognizable. Imperfect attempts at cicatrization

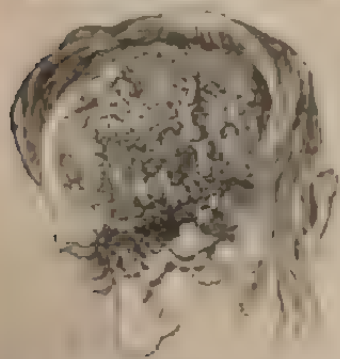

Fig. 418. — Rodent Ulcer. Perforation. (Skull and Exposure of Dura Mater.)

form a peculiar feature of the ulcer. At one part of its margin it ceases to spread, and a thin blue line of epithelium begins to extend over the raw

surface. It never, however, advances far; before long the spreading recommences at the edge of the apparently unaltered skin, and the thin layer of epithelium speedily disappears. This attempted cicatrization is never accompanied by any contraction of the sore. The want of contraction is a very peculiar feature of the disease. If half an eyelid is destroyed, the remaining half retains its normal position unaltered. Consequently signs of contraction may be taken during treatment to indicate that the growth has been successfully destroyed in part at least.

The course of the disease is always progressive; more rapid in the skin, more slow in the bones and less vascular tissues, as those of a cartilaginous and fibroid character—the pinna of the ear, the sclerotic, and the septum of the nose, for instance. When it attacks bones, it penetrates them, and sinks deeply into their softer parts. Moore has noticed that the morbid growth in front of the advancing disease is always most clearly marked in cancellated bone—in the diploë, for instance. The soft parts immediately contiguous to the disease are perfectly healthy and uninfiltated; and there is never, even after many years of progress, any sign of secondary affection of the lymphatic glands. Unless the progress of this ulcer be arrested by treatment, it is never interrupted, but will terminate in the death of the patient. This fatal termination may, however, be long delayed. The accompanying Fig. 418 is from a patient of mine who had suffered from the disease for nearly thirty years, but who was to all appearance in perfect health, although the skull was perforated, the dura mater exposed, and the pulsations of the brain distinctly visible.

Diagnosis.—The diagnosis has to be made from Epithelioma, Syphilis, and Lupus. The distinction from ordinary *epithelioma* is often at first difficult; but in the later stages the absence of glandular affection, the small amount of growth compared to the ulceration, and the prolonged course of the case, render the diagnosis easy. From *tertiary syphilis* it is clearly distinguished by the duration of the case; in syphilitic ulceration “the rate of destruction is measured by weeks; in rodent cancer, by years.” There is also an absence of all other signs of constitutional syphilis. From ordinary *lupus* it is distinguished by the age and healthy constitutional state of the patient, by the singleness of the ulcer, and the absence of the pink, scaly, or œdematous skin frequently found around lupus. Lupus may cicatrize and cease at any time; rodent ulcer never does. Lupus rarely causes death; rodent ulcer is always eventually fatal, if unrelieved by treatment.

Pathology.—The microscopic characters of the solid infiltrating substance have been examined by Moore, Hulke, and C. Warren, all of whom have found some parts which presented appearances identical with epithelioma. Moore found this in the diploë of the frontal bone, and Hulke in a part of the globe of the eye implicated in the disease. The greater part of the growth presents characters differing but little from those of ordinary granulation-tissue. Moore was of opinion that the growth commenced in all cases in a pimple identical in structure with epithelioma, but that this character was lost as the growth extended, but could be readily assumed again in “certain situations or in convenient textures.”

The conclusions at which Dr. Collins Warren arrives as the result of his researches, are, that rodent ulcer is a form of epithelial cancer; and that it differs from the more ordinary forms of epithelioma in the small size of the cells. The arrangement of these epithelial cells may be tubular and alveolar (Fig. 419).

Later observations by T. C. Fox, Thin, and others, have generally confirmed the observations of Moore, Hulke, and Warren; but these observers

being covered with a piece of water-dressing until the grayish slough that has been produced has separated, when the caustic may be reapplied as often as necessary. Besides the chloride of zinc, various other caustics may be had recourse to, each of which possesses some peculiar advantages. Nitric acid is useful, if the action required is not to be very deep; for, as it hardens and coagulates the tissues to which it is applied, it does not extend so far as the chloride. The acid nitrate of mercury presents the same advantage as the nitric acid, and other fluid caustics—that it can be applied into the fissures and hollows of the part into which the more solid caustics do not penetrate. The potassa fusa and Vienna paste are useful, so far as their destructive properties are concerned, but are somewhat uncontrollable, and apt to spread. The most convenient mode of applying them is to cut in a piece of plaster a hole of the exact size and shape of the ulcer, to apply this around its borders, then to cover the sore with a layer of potassa cum calce, one line in thickness, and over this to lay on another piece of plaster. In this way a considerable amount of caustic action may be induced, which will be limited exactly to the surface to which it has been applied. Of all these escharotics, the preference is to be given to the chloride of zinc; its action is more continuous and more controllable, and it appears to give a healthy stimulus to the subjacent structures.

2. Excision of the whole of the ulcer may often be very advantageously practised, especially when it is situated on the cheek, eyelid, eye, or forehead; and the gap left may be filled in by some of those plastic processes that will be described when we come to speak of the Plastic Surgery of the Face.

3. When the ulcer has attained a large size, when it is complicated in its outline, and irregular in its depth, the question arises whether surgery offers any resource, or whether the patient should be left slowly and miserably to die.

In these extreme cases, even, something may be done to prolong life and to relieve suffering, even if no cure be ultimately expected. Moore proved that, unless the brain be implicated, or some large vessel involved, something can usually be done at least to arrest the rapidity of the growth. The method which he adopted was a combined use of the knife and of chloride of zinc. By these means he removed in some cases the whole of the affected parts, leaving a huge chasm in the face, and even in one case exposing the dura mater for a considerable extent over the roof of the orbit. The operations were done on no regular plan, the incisions being directed solely by the shape of the growth, and no attempt being made to repair the deformity left. The results of these operations were, on the whole, favorable. Out of six cases three recovered, and three others received decided benefit, but were not permanently cured. In all the cases in which the chloride of zinc came into actual contact with the dura mater, epileptiform fits occurred, but only of a temporary character.

When the disease is situated in an extremity, and the cancellous end of a bone especially is involved, as when it dips into and erodes the head of the tibia or the lower end of the radius, amputation would be the proper and only advantageous procedure.

When the disease is so extensive, or so situated, that absolutely nothing in an operative way can be done, the Surgeon must content himself by covering up the raw surface with lint soaked in glycerine and water, and protected by oiled silk. Iodoform, either dusted on or applied as an ointment, composed of one drachm of the powder to an ounce of vaseline to which a small quantity of eucalyptus oil may be added, will usually be found the best application.

CANCER OF THE SKIN may be either primary or secondary. **Primary Cancer**, if we exclude the **Indolent Ulcer**, always assumes the form of the

Fig. 420. — Cancerous Ulcer of the Leg

Squamous Epithelioma. The structure and history of this have already been described. It is usually seated about the lips, face, and scrotum, and at the orifices of the mucous canals. It may in rare cases arise from malignant transformation of an atheromatous cyst (p. 334, vol. i.). Epithelial cancer may originate also in an old scar or ulcer.

In this way it may occur upon almost any part of the body; I have seen it on the back, breast, fingers, hand, thigh, and sole of the foot. It then forms a foul ulcer, the floor of which is gray or sloughy, and often covered with large warty granulations and protuberant masses. The base is indurated, the edges raised and everted, and often papillary in structure (Fig. 420). The discharge is thin and scanty, and unless the sore is treated by antiseptic applications it becomes horribly offensive.

Secondary Cancer of the Skin may arise from direct extension from a primary growth or from a secondary glandular tumor. The most marked examples are commonly met with in cancer of the breast. In this disease, after the primary tumor has reached the surface, numerous smooth, elevated tubercles of a dusky red or brownish color, may appear dotted in the skin for many inches around the part first implicated. Each of these is a small scirrhous cancer identical in structure with the primary growth in the mammary gland.

In other cases, fortunately rare, the skin covering the side of the chest is widely infiltrated by the malignant growth. It becomes smooth, of a brownish-red color, and hard and rigid, like a piece of leather, from which it has received the name of the **cancerous cuirass**.

Sarcomata of the Skin—Various forms of sarcoma are met with in the skin. *Spindle-celled* and *round-celled sarcoma* are seen here as in all other fibrous structures. Two forms, however, show a special predilection for the skin—the *melanotic*, and the *alveolar*. *Melanotic sarcoma* often commences in some pigmented spot, such as a mole. It forms a rounded tumor, smooth on the surface, and dark brown or black in color. It is intensely malignant, and however early it may be removed, it is very apt to return both locally and in internal organs. If not removed, it gradually increases and at last ulcerates, but before this takes place it often reaches a considerable size. I have met with two instances of late of this disease, one on the foot, the other on the hand, of ladies both above seventy years of age. Some time after removal in both cases brownish-black patches looking like stains with Indian ink appeared on the skin in the neighborhood of the cicatrix. These gradually developed into new tumors. In one case hundreds of these formed up the leg, varying in size from a pea to a walnut. They slowly ulcerated and life was destroyed, probably by secondary growth in the vessels, after a period of about four years from the primary manifestation of the disease.

Alveolar Sarcoma of the skin is rare. Its structure and general character are already described (p. 326, vol. i.). It is probably this tumor described by Scarpa as the "scirrhous wart," as from its hardness and general malignancy it usually manifests, it closely resembles a malignant tumor of the skin, whether a cancer or a

sarcoma, consists in its excision or in amputation of the limb affected. Its removal by excision should be effected as soon as its true characters have declared themselves; provided it be of such a size, and so situated, that it can be freely removed with a sufficient stratum of subjacent healthy parts, and a wide border of surrounding skin. Should it be so situated that its excision through surrounding healthy tissue is not practicable, the limb must be amputated, as was done in the case depicted in Fig. 420. In such circumstances the limb may be removed at no great distance above the disease; it not being necessary, as in cases of cancer of the extremities in which the bones are affected, to allow a joint to intervene between the seat of operation and the malignant growth.

SIMPLE TUMORS OF THE SKIN.—

Fibroma.—Circumscribed fibrous tumors are occasionally met with in the skin, but are not common.

Keloid is a fibroid growth not encapsuled, but fusing with the healthy skin at its edges. It forms a flat tumor, raised about a line above the surrounding healthy skin. It is oval, rounded, or irregular, and branching or radiating in form. The surface is smooth, and white or pink in tint. It is firm and elastic in consistence. It arises without known cause and most frequently upon the trunk or extremities in persons otherwise healthy. It is seldom painful, but may give rise to itching and burning sensations. It extends slowly, and although covering a wider area sometimes seems to have undergone a process of contraction like a scar, the surrounding skin being drawn in and wrinkled or puckered. After reaching a certain size it ceases to grow. It has no tendency to ulcerate or to degenerative changes. The *Treatment* is merely to allay uneasy sensations by sedative applications. If excised, it almost certainly returns in the scar.

Closely allied to true keloid are those fibroid growths that have a tendency to sprout up in scars, constituting **False Keloid**. It was described also by Sir Caesar Hawkins under **Warty Tumors of Cicatrices**.

This morbid condition appears to be simply an abnormal increase in the activity of the development of the cicatricial tissue, which springs up with great luxuriance. They are especially apt to follow the irregular cicatrization of burns, more particularly in children. I have, however, seen them in the adult, occasioned both in this way and by the irritation of a blister. The warty cicatricial tissue develops chiefly on the chest and neck, and is commonly attended by much itching and tingling, often of a most distressing character. It is very vascular, bleeding freely when incised. The *Treatment* of these growths is not satisfactory. As a rule, they may safely be let alone. If they cause any annoyance, the only treatment is to remove them by the knife if they are so situated as to make this possible, but most commonly the new scar assumes the same unhealthy condition.

The disease known as **Molluscum Fibrosum**, in which enormous pendulous tumors composed of hypertrophied skin and subcutaneous tissue, has already been described (p. 944, vol. i.).

Osteomata of the Skin have been described. They are always atheromatous cysts, the walls of which have undergone calcification, and occasionally true ossification in parts (p. 933, vol. i.).

Adenoma of the Skin, arising both from the sweat-glands and sebaceous follicles, have been occasionally met with. They are, however, very rare. When arising in connection with the sebaceous follicles, they form lobulated masses of some size, which after growing for many years may ulcerate and resemble epithelioma in appearance. On microscopic examination, they are found to be composed of a structure resembling a number of greatly enlarged follicles bound together by a vascular connective tissue.

Atheromatous and other Cysts have already been described (p. 131, vol. i.), and **Nævi** will be described in a subsequent chapter with Diseases of the Bloodvessels.

Moles are pigmented patches of variable size in the skin, and always of congenital origin. They are often raised above the surface of the surrounding skin and covered with hair, sometimes long and coarse. They cannot be properly classed as tumors, as they show no tendency to grow out of proportion to the rest of the body. In later life, however, a mole not unfrequently forms the starting-point of a tumor. It may gradually increase in size, becoming more and more prominent, and sometimes pedunculated. It may thus form a tumor, usually lobulated or papillary, and more or less darkly pigmented. Finally, from the friction of the clothes it may ulcerate and become very troublesome. A mole also not uncommonly forms the seat of origin of a sarcoma, or more rarely of a squamous epithelioma. A mole requires no treatment unless it become affected by one of the complications above mentioned, when it must be at once excised. The Surgeon is often consulted as to the possibility of removing a disfiguring mole from the face. There is no method by which this can be done without leaving a scar in its place, but if the patient prefer this to the pigmented patch, the mole may be destroyed by caustics. Nitric acid and potassa fusa are the two most efficient applications but they should not be applied in such quantity as to destroy the whole skin, otherwise a puckered and rigid cicatrix will result.

Papillomata of the Skin, or Warts, consist of elongated papillæ, covered by strata of thickened and hardened cuticle, usually situated about the hands and face, and chiefly affecting young people; they appear in many cases to be simple overgrowths of the cutaneous structures, coming and going without any evident cause. In other cases they are more permanent, becoming hardened and dark in color, and continuing perhaps through life.

The *Treatment* of warts is usually sufficiently simple. They may be readily destroyed by the application of caustics or astringents; among the most useful of these I have found the concentrated acetic acid and the tincture of the esquischloride of iron. Brodie recommends a solution of a drachm of arsenious acid in half an ounce of nitric acid. In some cases they may be ligatured or snipped off with advantage.

Corns consist of thickened masses of epithelium accumulated on those points on which undue pressure or friction has been exercised. They result from an overgrowth of the epithelium, consequent upon the abnormal stimulation to which the part is exposed. This is accompanied by some enlargement of the papillæ. The mass of epithelium is hard, dry, and scaly. In the central parts it may lead to some atrophy of the papillæ from pressure, and consequently the horny mass assumes a conical form, with its apex downwards, pressing on the sensitive cutis beneath, and thus causing considerable pain. When the corn is situated in places where the secretions of the skin accumulate and keep it moist, as between the toes, the excessive epithelium forms a soft pulpy mass which is easily removed, and the enlargement of the papillæ is then very evident.

Under old and very thickened corns, it is stated by Brodie that a small bursa is occasionally found; this bursa may suppurate, and become very painful. Corns are at all times sufficiently painful, but become especially so if inflammation or suppuration take place beneath them: the accumulation of a small drop of pus under the thickened cuticle, which prevents its escape, giving rise to very intense agony, and causing oedema and redness extending from the toe to the foot, and sometimes up the leg. There is a special form of warty corn that I have seen only in the sole of the foot, and which may become the source of the greatest possible pain and inconvenience

to the patient, preventing his walking, and in fact completely crippling him. This corn is usually of small size and circular in shape, the neighboring cuticle being always greatly thickened and hardened. It is extremely sensitive to the touch, the patient shrinking when it is pressed upon, as if an exposed nerve had been injured. On slicing it down with a scalpel, it will be found to be composed of soft, tough, and white epidermis, arranged in tufts or small columns, in the centre of each of which a minute black dot is perceptible. Each tuft appears to be an elongated and thickened papilla, and the black speck is a small point of coagulated blood which has been effused into it. Around the depression in which each of these corns is seated, the hardened cuticle forms a kind of wall.

The *Treatment* of ordinary corns consists in shaving or rasping them down so as to prevent the deep layers of cuticle, retained by the indurated superficial ones, from giving rise to pain by pressure on the papillæ of the cutis. The cuticle may be previously softened by dressing the toe with wet lint covered with gutta-percha tissue. Relief may be afforded also by removing all pressure from bearing upon the corn, by attention to the shape of the shoe, and by wearing a piece of soft leather or of amadou, having a hole cut in the centre into which the corn projects. A soft corn between the toes is best treated by the application of tincture of belladonna after clearing away the sodden epithelium with soap and water. It is well to avoid the application of caustics to ordinary corns; injurious consequences being often produced by these agents, especially in elderly people, in whom fatal gangrenous inflammation may be excited by their action.

The painful papillated corn of the sole of the foot is the only form to which an escharotic can be applied, and in this no other treatment is of any use. I have found the application of either fuming nitric acid or potassa fusa, so as to destroy it thoroughly, to be the best and speediest remedy; and as this corn always occurs in young people no danger attends their use.

If a corn suppurates, it must be softened by water dressing and shaved down, and the drop of pus let out by puncture with a lancet, when immediate relief from pain will result. If the pus is not thus let out, it is unable to point through the indurated cuticle, and may burrow beneath the skin for some distance before finding an exit. In such case a troublesome sinus is left which can sometimes be closed by the injection of stimulating lotions, or by passing a seton of two silk threads through it, but more often laying it open is the only efficient treatment.

PERFORATING ULCER OF THE FOOT.—This, though not in reality a disease of the skin, is perhaps most conveniently considered here. The disease seems usually to commence by a corn situated on the sole of the foot opposite the head of one of the metatarsal bones, usually the first. This, in some cases apparently as the result of some injury, becomes inflamed and suppurates, and a sinus is left opening through the thickened cuticle. If a probe be passed into this, it will be found to lead to dry and bare bone on one of the phalangeal or metatarsal bones. The discharge is scanty and scarcely purulent. The ulceration may extend, forming a sore an inch or more in diameter. This is covered by feeble or unhealthy granulations. The disease is painless, and on further examination the foot will be found to be more or less widely anæsthetic. The anæsthesia may extend up the leg, but it is never associated with motor paralysis. The tendency of the disease is slowly to extend, causing further destruction of the bones and possibly completely perforating the foot. The foot is cold, and in most cases is prone to sweat profusely, the perspiration being very offensive. Both feet may be affected, and a similar disease has been seen in the hand.

Michaud, Sonnenburg, Duplay, and more lately Savory and Butlin, have

pointed out that the disease is associated in many cases with thickening of the endoneurium and atrophy of the fibres of the nerves leading to the affected spot. Savory and Butlin have brought forward evidence to show also that the sensory fibres are chiefly, if not solely, affected. Similar ulcerations are met with in some cases of locomotor ataxy. It may therefore be concluded that the primary cause of the disease is impairment of nutrition consequent upon degenerative changes taking place either in the nerves leading to the affected parts or in that portion of the sensory columns of the cord that is in communication with the foot. In some respects it resembles the disease known as anæsthetic leprosy.

The *Treatment* consists in amputation of the affected part. In order that this operation may be effective, it should be done above the area of anæsthesia in the foot or leg.

CHAPTER XXXVIII.

DISEASES OF THE NERVOUS SYSTEM.

NEURITIS.

Inflammation of the Nerves, or rather of the Neurilemma, is not of very unfrequent occurrence, being usually the result of rheumatism, of wounds, or of strains. When Neuritis is rheumatic, it affects principally the nerves of the face and the lower extremity.

SYMPTOMS — These consist of tenderness on pressure along the course of the nerve, and severe continuous pains running down its trunk and ramifying along its branches, with occasional violent exacerbations, especially on moving or touching the part, and at night. In very rare cases the disease may assume an acute form, with some swelling along the course of the nerve, and slight pyrexia. Ordinarily the affection is chronic. It is one of the causes of neuralgia. On examination after death in acute cases the sheath of the nerve will be found injected and swollen from inflammatory exudation. In chronic cases the neurilemma may be found indurated and increased in quantity, the nerve fibres being more or less compressed by the new fibroid tissue. Traumatic neuritis has been already fully described (vol. i. p. 477).

Treatment — In acute cases this consists in the employment of antiphlogistic means: cupping or the application of leeches, according to the situation, and poppy or belladonna fomentations. In chronic cases blistering or the application of mustard plasters along the line of the nerve usually gives relief. The part in which the affected nerve is situated must, if possible, be kept at perfect rest. When the affection is rheumatic, salicylate of soda is frequently of great use, in some cases the acetous extract of colchicum is the best remedy; when it is more chronic, and the pain is chiefly nocturnal, iodide of potassium may advantageously be given.

SCIATICA.

The characteristic feature of *sciatica* is pain of a neuralgic character in the course of the great sciatic nerve. The affection is believed in the great majority of cases to be due to chronic rheumatic inflammation of the sheath

of the nerve, and some thickening of the neurilemma has been recognized after death in a few cases. In other cases pain of a similar character may be the result of pressure on the nerve by tumors in the pelvis or gluteal region, or occasionally from affection of the cord or disease of the spine in the lower lumbar or sacral region. Sciatica is most common in young adults, and frequently arises from exposure to cold or damp.

The *Symptoms* of sciatica are pain in the buttock, back of the thigh, and the leg below the knee. The pain may amount merely to uneasiness, or be intense and paroxysmal. It is usually aggravated by movement, often to such an extent as to render locomotion impossible. When the pain extends to the foot it is felt chiefly on the outer side, the inner being supplied by the long saphenous nerve from the lumbar plexus. By pressing with the point of the finger, tenderness will be found in the course of the nerve. This is most marked in the hollow between the trochanter and the tuberosity of the ischium, and down the back of the thigh. The external popliteal nerve is also sometimes acutely tender where it winds round the upper end of the fibula. When the patient is lying on his back, if the limb be raised with the knee extended, acute pain is felt in the buttock as soon as the sciatic nerve becomes tense. If now the knee be flexed so as to relax the nerve, flexion of the hip can be carried considerably further without pain. Numbness in some of the parts supplied by the nerve is not uncommon, especially on the outer side of the foot. Motor paralysis never results from simple sciatica, but there may be some weakness or even wasting of the limb from want of use. The affection is very chronic, often lasting many weeks or even months.

The *Diagnosis* of sciatica is made by attention to the above symptoms. It is most frequently confounded with strumous disease or chronic rheumatic arthritis of the hip. The distinction is in most cases easily made by observing that the movements of the hip-joint are free and unaccompanied by pain, unless flexion is carried to such an extent as to render the nerve tense. In rheumatoid arthritis the grating felt in the joint on movement will usually indicate the nature of the disease; with the "lightning pains" of locomotor ataxy it must not be confounded. In all cases of sciatica a careful examination of the buttock must be made for a tumor in that region; the lower part of the spine must be examined for signs of caries, and the finger might be passed into the rectum to feel for a pelvic tumor, as in these conditions local treatment directed to the course of the nerve could be of but little use.

Treatment.—The constitutional treatment already described for rheumatic neuritis must be adopted. The limb must be wrapped in flannel. Counter-irritation along the line of the nerve in the early stages by mustard-plasters, and later on by blisters, is most useful. Hot baths usually give considerable relief. Stimulating applications, as the ammonia or compound camphor liniment, may be of use; and sedatives, as the opium or belladonna liniment, may ease the pain, but they do little to cure. Hypodermic injections of morphia should be resorted to only when the patient is suffering from want of sleep due to the pain. They exert no curative influence.

If the constitutional treatment and external applications fail, as they very frequently do, two modes of treatment may be adopted—acupuncture and nerve-stretching.

Acupuncture is thus performed. The patient is laid on his face, and the tender points of the nerve found by pressure. Long fine needles are then thrust in so as, if possible, to puncture the nerve. When the needle touches the nerve, the patient complains of a sudden pain down the thigh. The number of the needles used should not exceed six. They may be left in for a few minutes. This treatment sometimes gives permanent relief.

Our last resource is, however, **Stretching the Sciatic Nerve**. This operation has been more successful in sciatica than in any other painful affection for which it has been undertaken. Nocht has collected 24 cases, of these 16 were quickly, 5 slowly, relieved, in 2 the operation failed, and 1 died. Marshall finds that of 9 cases which occurred in University College Hospital, 4 were decidedly improved, 4 partially cured, and 1 failed.

The operation is thus performed. The patient is laid upon his face, and a vertical incision, about three inches in length, is made a little above the middle of the back of the thigh. The deep fascia is opened, and the contiguous borders of the semi-tendinosus and biceps are separated with the finger. The wound being now held open by copper spatulae, the sciatic nerve comes into view and is raised out of the wound by passing the finger beneath it, the knee being flexed to relieve it from tension. It is then pulled forcibly in both directions. Marshall has demonstrated that any force which can be applied while holding the nerve between the finger and thumb may safely be used. The experiments of Johnson, Trombetta, Ceccherelli, and others, have shown that the breaking strain of a healthy nerve is never under eighty pounds. The wound after the operation must be carefully drained and dressed by some antiseptic method, and it is better to apply an anterior splint for a week or ten days.

Some Surgeons prefer exposing the nerve at a higher point, below the lower border of the gluteus maximus. If the operation be performed at this point, the whole of the ham-string muscles must be drawn together to the inner side of the wound, and the nerve sought for external to them. If necessary, the lower fibres of the gluteus may be divided. There is no particular advantage in this mode of operating, and the resulting wound is deeper and more difficult to treat, owing to its situation.

Trombetta and Billroth have suggested stretching the nerve by means of forcible flexion of the hip with the knee extended and the foot flexed. That a very great strain can be put upon the nerve in this way is evident, and the method might very well be tried before proceeding to the more severe operation just described. It is best done by flexing the thigh fully on to the abdomen with the knee bent, and then, while the thigh is fixed, extending the leg.

The mode of action of nerve-stretching in sciatica is uncertain. The conductivity of the sciatic nerve is not affected at all, or only to a very slight degree, by the force used in the operation. It has been suggested that it acts by breaking down adhesions either amongst the fibres or between the sheath and surrounding structures. Marshall believes it acts by stretching or even rupturing the small *nervi nervorum* ramifying in the neurilemma and in the epineurium, which must be more or less implicated and pressed upon by any inflammatory growth or exudation in chronic neuritis.

NEURALGIA.

Neuralgia frequently occurs in surgical practice, either complicating other diseases, or as a distinct affection simulating closely various organic lesions, more especially of joints and bones.

Symptoms—The pain in neuralgia is the essential symptom. It may be of two kinds; either following anatomically the course of a nerve and the distribution of its filaments; or affecting a considerable portion of the surface without reference to any special nerve. It is of all degrees of severity, sometimes moderate, sometimes unbearable, even by those who possess the greatest fortitude; when severe, it usually comes on suddenly, a kind of shock, and continues of a sharp, darting, or tearing char-

acter, coursing along the trunk or ramifications of the affected nerve, the distribution of which may often be distinctly indicated by the direction the pain takes. It is often accompanied by other sensations, such as a tickling, smarting, or creeping feeling on the affected surface; it is in some instances relieved by pressure, in others increased by the slightest touch or movement of the part. Occasionally there is spasm in the muscles supplied by the affected nerve; in other cases, there are heat and redness of the surface, with increased secretion from the neighboring organs, as a flow of saliva or tears when the nerves of the jaw or eye are implicated. The duration of an attack may vary from a few moments to many days or months. The pain is most commonly intermittent or remittent; it is often irregularly so, but in some instances the periodicity is well marked.

SITUATIONS.—This disease may affect almost any part of the body; it is most commonly seated distinctly in the trunk and branches of a nerve. The divisions of the fifth pair are the most frequent seat of neuralgia; the pain may extend to the whole of the branches of this nerve on one side of the head and face, but more commonly it is confined to one of its principal divisions, such as the infraorbital, which is especially liable to be affected; in many instances it is seated in the temporal and dental nerves. Not unfrequently some of the terminal twigs alone of one of these nerves become the seat of intense pain; thus occasionally the affection is found limited to a patch on the cheek, brow, or temple, from which it scarcely ever shifts. The posterior branches of the dorsal spinal nerves, and the intercostals, are also very commonly affected, though not to the same extent as the fifth pair. In other cases the whole of an organ, or part, becomes the seat of neuralgia, though no one nerve may appear to be distinctly implicated; thus the testes, the breast, the uterine organs, or one of the larger joints, as the hip or knee, are occasionally the seats of severe suffering of this kind. Extreme cutaneous sensibility is a marked feature in some cases; the patient wincing and suffering severely whenever the skin is pinched or touched, however lightly.

CAUSES.—The causes of this painful affection are very various; they may be constitutional or local. It seldom occurs in strong and healthy individuals, but is almost invariably associated with want of power, unless it be occasioned by some local mechanical cause. *Depressing influences* of all kinds are especially apt to produce it; thus, debilitating diseases, mental depression, and particularly exposure to malaria, are common occasioning causes; those forms of the disease that arise from malarial influences, or from exposure to simple cold and wet, usually assume a very intermitting or periodical character, and are commonly seated in the nerves of the head. The *hysterical temperament* very frequently disposes to the spinal and articular forms of neuralgia. There is no constitutional condition with which neuralgia is more frequently associated than with anemia; hence its frequency in females. As Romberg somewhat poetically says, "Neuralgia is the prayer of the nerve for healthy blood." Various sources of *peripheral irritation*, as loaded bowels, the irritation of worms, carious teeth, uterine diseases, and calculus, may be recognized as producing some of the more obscure varieties of the disease.

Neuralgia may arise also from any compression exercised upon the trunk of a nerve; and in this way, indeed, some of the more intractable forms of the affection have their origin. Thus, thickening of the neurilemma, the pressure of a tumor of any kind, or of a piece of dead bone, may give rise to the most intense pain in the part supplied by the irritated nerve; and it is not improbable that, in many of the cases of neuralgia in the branches of the fifth nerve, pain may be owing to periosteal inflammation, or to some other disease of the osseous canals through which the divisions of the nerve pass.

DIAGNOSIS.—The diagnosis of neuralgia, though usually effected without difficulty, is in some cases a little embarrassing, as the pain may occasionally simulate that of organic disease or inflammation of the part. From organic disease of the part that is the seat of suffering, such as the hip, the knee, the testis, or the breast, this disease may usually be distinguished by the existence of heightened cutaneous sensibility, the existence of the hysterical temperament, and the absence of the other signs that would accompany lesion of structure in the part affected. From inflammation the diagnosis is usually sufficiently easy, by attending to the intermittent character of the neuralgic pain, to its occurrence in hysterical temperaments, and to the absence of the constitutional symptoms of inflammation. But occasionally when local inflammatory irritation is conjoined with the neuralgia, the diagnosis is difficult. Here the presence of cutaneous hyperæsthesia and the relief of the pain by firm pressure will indicate neuralgia; whereas, in inflammation, there is no tenderness of surface, but the suffering is aggravated by deep pressure.

TREATMENT.—The treatment of neuralgia must have reference to its cause, and will be successful or not according as this may be more or less readily removed. So long as the conditions that primarily occasion the disease subsist, the pain is likely to continue; and if these conditions be irremovable, the disease may be looked upon as necessarily incurable, though the suffering may be alleviated by appropriate means. When it arises from any central nervous affection, there may be fear of the ultimate occurrence of disease of a more serious type, such as epilepsy, insanity, etc.

When it occurs as the consequence of anemia, or in the hysterical temperament, the administration of the more stimulating and stronger preparations of iron such as the sulphate or the perchloride, or the *mistura ferri*, either alone or in combination with quinine, with attention to the bowels and of the uterine functions, and a general tonic regimen, directed to brace and improve the general health, such as sea-bathing, cold douches or cold sponging, will be of essential service. In some of these cases the combinations of zinc, especially the valerianate, with the iron, will remove the disease when iron does not influence it much. At the same time, the application of belladonna or acetate plasters, or the use of those liniments may be of service. When the neuralgia is distinctly periodical, quinine in full doses, or the liquor arsenicalis, will usually afford a speedy cure. When it is rheumatic, occurring in debilitated subjects, it is attended by distinct nocturnal exacerbations of pain, no remedy will produce great an impression upon it as the iodide of potassium, especially when combined in combination with quinine. In the more severe and obstinate cases of the disease, relief may be occasionally obtained by attending to the state of the liver and digestive organs, by a course of some of the purgative mineral waters, and by the occasional administration of the more powerful tonic remedies.

The applications of a sedative kind, such as chloroform, belladonna, opium, etc., are often useful adjuncts to constitutional treatment. By the readiest mode of affording relief locally is the hypodermic injection. More than from one-sixth to a quarter of a grain of morphia should at first be used at one time, and the action of this small dose is often very powerful. More than this, it is unsafe to begin with; but the quantity may be enor-
mously increased. I have had a patient who, to relieve the pains attending
of the rectum and anus, required no less than six grains to be injected
with half an hour, for several months. In some cases a single injection has
neuralgia which has resisted all other means. Relief may often be
obtained by the use of electricity in the form of the continuous current. The

positive sponge must be applied to some convenient place near the seat of pain, while the neuralgic spot is gently rubbed with the negative until the skin is reddened. In exceptional cases the relief is permanent.

In many cases all these means, however, are unfortunately unavailing, and the sufferer is doomed to an existence of almost constant pain, except at times when the disease appears to cease of itself, or has its intensity blunted by the administration of the more powerful sedatives, such as morphia hypodermically, or veratria, aconite, or atropine externally. In these distressing cases the sufferer is ready to grasp at any means of relief that is held out to him; and stretching of the affected nerve is now frequently undertaken in the hope of relieving, if not completely removing the affection. This operation has already been described (p. 477, vol. i.). It was there pointed out that the effect produced differs considerably, according to the size of the nerve operated on. In small nerves, such as those of the face, the conductivity of the nerve is abolished as completely as if it had been divided, but as its continuity is not interrupted, repair always takes place, and after a time its function is restored. In the larger nerves, even when considerable force is used, the conductivity is not completely abolished, although it may be modified for a time. It is only when great force is used that the breaking up of the medullary sheath observed by Leuterman and Horsley takes place. We have seen that in sciatica, in which the disease is seated in the actual trunk of the nerve, great benefit is usually derived from nerve-stretching, and probably the same result may be hoped for when a similar condition exists in other nerves. In the majority of cases of neuralgia, however, the cause is either some peripheral irritation of the terminal branches or some central disease, and in these but little is to be expected from the operation. In the former case there might be temporary relief until repair of the nerve was accomplished; and in the latter, although experience has shown that there is sometimes some improvement, this is only of the most temporary character.

When stretching has failed, section of the affected nerve is not unfrequently recommended as a last chance of the removal of the disease. Simple section of the smaller nerves is now replaced by stretching, which, as has just been stated, temporarily abolishes their conductivity. Division is undertaken with the intention of permanently destroying the continuity of the nerve, and to insure this about a third or half an inch of the trunk must be cut away. As with stretching, however, it is clear that the operation, though occasionally productive of temporary relief, cannot in most cases be expected to benefit the patient permanently; for by it the cause of the neuralgia is not removed, and it can consequently be of service only when the pain is peripheral, occasioned by some local irritation existing between the part cut and the terminal branches of the nerve. If the neuralgia depend on any central cause, or on local irritation existing higher up than the point divided, the operation must eventually be useless. Thus, if the source of irritation exist in the terminal branches of the infraorbital nerve, the division of this trunk might be useful; but if the pain be occasioned by any pressure to which this nerve may be subjected in its passage through its canal by a carious state of the bones, or by disease of the periosteum, it would be unavailing; though it is a remarkable fact, that it not unfrequently happens that there is after these operations a temporary cessation of pain for a few weeks or months. In some of these cases, however, the pain shifts its seat from the branch operated on to another division of the same trunk; thus, if the infraorbital have been divided, the inferior dental or submental nerve becomes the seat of pain. Or this may ascend, as it were, to the point at which the nerve was divided; thus, after amputation for neuralgia of the knee, the pain may return in the stump, and again when this is removed a second or even a third time.

DIAGNOSIS.—The diagnosis of neuralgia, though usually effected without any difficulty, is in some cases a little embarrassing, as the pain may occasionally simulate that of organic disease or inflammation of the part. From *organic disease* of the part that is the seat of suffering, such as the hip, the knee, the testis, or the breast, this disease may usually be distinguished by the coexistence of heightened cutaneous sensibility, the existence of the hysterical temperament, and the absence of the other signs that would accompany lesion of structure in the part affected. From *inflammation* the diagnosis is usually sufficiently easy, by attending to the intermittent character of the neuralgic pain, to its occurrence in hysterical temperaments, and to the absence of the constitutional symptoms of inflammation. But occasionally, when local inflammatory irritation is conjoined with the neuralgia, the diagnosis is difficult. Here the presence of cutaneous hyperæsthesia and the relief of the pain by firm pressure will indicate neuralgia; whereas, in inflammation, there is no tenderness of surface, but the suffering is aggravated by deep pressure.

TREATMENT.—The treatment of neuralgia must have reference to its cause, and will be successful or not according as this may be more or less readily removed. So long as the conditions that primarily occasion the disease subsist, the pain is likely to continue; and if these conditions be irremovable, the disease may be looked upon as necessarily incurable, though the suffering may be alleviated by appropriate means. When it arises from any central nervous affection, there may be fear of the ultimate occurrence of disease of a more serious type, such as epilepsy, insanity, etc.

When it occurs as the consequence of anæmia, or in the hysterical temperament, the administration of the more stimulating and stronger preparations of iron, such as the sulphate or the perchloride, or the *mistura ferri composita*, either alone or in combination with quinine, with attention to the state of the bowels and of the uterine functions, and a general tonic regimen calculated to brace and improve the general health, such as sea-bathing, the cold douche or cold sponging, will be of essential service. In some of these cases the combinations of zinc, especially the valerianate, with the fetid gums, will remove the disease when iron does not influence it much. At the same time, the application of belladonna or aconite plasters, or the inunction of these liniments may be of service. When the neuralgia is distinctly periodical, quinine in full doses, or the liquor arsenicalis, will usually effect a speedy cure. When it is rheumatic, occurring in debilitated subjects, and attended by distinct nocturnal exacerbations of pain, no remedy exercises so great an impression upon it as the iodide of potassium, especially when administered in combination with quinine. In the more severe and protracted forms of the disease, relief may be occasionally obtained by attention to the state of the liver and digestive organs, by a course of some of the more purgative mineral waters, and by the occasional administration of albetics, followed by tonic remedies.

Local applications of a sedative kind, such as chloroform, belladonna, acetate, opium, etc., are often useful adjuncts to constitutional treatment. By far the readiest mode of affording relief locally is the hypodermic injection. Not more than from one-sixth to a quarter of a grain of morphia should at first be used at one time, and the action of this small dose is often very powerful. More than this, it is unsafe to begin with; but the quantity may be enormously increased. I have had a patient who, to relieve the pains attending cancer of the rectum and anus, required no less than six grains to be injected every twelfth hour, for several months. In some cases a single injection has cured neuralgia which has resisted all other means. Relief may often be obtained by the use of electricity in the form of the continuous current. The

positive sponge must be applied to some convenient place near the seat of pain, while the neuralgic spot is gently rubbed with the negative until the skin is reddened. In exceptional cases the relief is permanent.

In many cases all these means, however, are unfortunately unavailing, and the sufferer is doomed to an existence of almost constant pain, except at times when the disease appears to cease of itself, or has its intensity blunted by the administration of the more powerful sedatives, such as morphia hypodermically, or veratrin, aconite, or atropine externally. In these distressing cases the sufferer is ready to grasp at any means of relief that is held out to him; and stretching of the affected nerve is now frequently undertaken in the hope of relieving, if not completely removing the affection. This operation has already been described (p. 477, vol. i.). It was there pointed out that the effect produced differs considerably, according to the size of the nerve operated on. In small nerves, such as those of the face, the conductivity of the nerve is abolished as completely as if it had been divided, but as its continuity is not interrupted, repair always takes place, and after a time its function is restored. In the larger nerves, even when considerable force is used, the conductivity is not completely abolished, although it may be modified for a time. It is only when great force is used that the breaking up of the medullary sheath observed by Leuterman and Horsley takes place. We have seen that in sciatica, in which the disease is seated in the actual trunk of the nerve, great benefit is usually derived from nerve-stretching, and probably the same result may be hoped for when a similar condition exists in other nerves. In the majority of cases of neuralgia, however, the cause is either some peripheral irritation of the terminal branches or some central disease, and in these but little is to be expected from the operation. In the former case there might be temporary relief until repair of the nerve was accomplished; and in the latter, although experience has shown that there is sometimes some improvement, this is only of the most temporary character.

When stretching has failed, section of the affected nerve is not unfrequently recommended as a last chance of the removal of the disease. Simple section of the smaller nerves is now replaced by stretching, which, as has just been stated, temporarily abolishes their conductivity. Division is undertaken with the intention of permanently destroying the continuity of the nerve, and to insure this about a third or half an inch of the trunk must be cut away. As with stretching, however, it is clear that the operation, though occasionally productive of temporary relief, cannot in most cases be expected to benefit the patient permanently; for by it the cause of the neuralgia is not removed, and it can consequently be of service only when the pain is peripheral, occasioned by some local irritation existing between the part cut and the terminal branches of the nerve. If the neuralgia depend on any central cause, or on local irritation existing higher up than the point divided, the operation must eventually be useless. Thus, if the source of irritation exist in the terminal branches of the infraorbital nerve, the division of this trunk might be useful; but if the pain be occasioned by any pressure to which this nerve may be subjected in its passage through its canal by a carious state of the bones, or by disease of the periosteum, it would be unavailing; though it is a remarkable fact, that it not unfrequently happens that there is after these operations a temporary cessation of pain for a few weeks or months. In some of these cases, however, the pain shifts its seat from the branch operated on to another division of the same trunk; thus, if the infraorbital have been divided, the inferior dental or submental nerve becomes the seat of pain. Or this may ascend, as it were, to the point at which the nerve was divided; thus, after amputation for neuralgia of the knee, the pain may return in the stump, and again when this is removed a second or even a third time.

Facial Neuralgia is the most common form of the disease. It may affect any one of the branches of the fifth, or in extreme cases almost every part at the same time. The various divisions of this nerve have, therefore, been most frequently stretched or divided for neuralgia, and it is necessary briefly to describe the operative procedure required in the case of each nerve.

First or Ophthalmic Division of the Fifth.—It is evident that the frontal branch of this nerve is the only part that can be either stretched or divided. The frontal divides about the middle of the orbit into the supratrochlear and supraorbital branches. The supratrochlear is too small, and, as a rule, too much broken up into branches to be isolated and stretched. The supraorbital, on the other hand, leaves the orbit usually as a single trunk, and can be isolated without difficulty. The position of the nerve is recognized by feeling for the supraorbital notch, through which it passes. The nerve may be stretched subcutaneously by making a small puncture with a tenotome about a quarter of an inch on one side of the notch. A blunt hook is inserted through this and forcibly scraped along the bone until its point has passed the line of the nerve. The skin of the forehead must be pulled upwards so as to make it tense, and there will then be no difficulty in ascertaining by the sense of resistance whether the nerve has been hooked or not. If it be felt upon the hook, the skin of the forehead being pulled forcibly upwards, the nerve may be firmly stretched.

Section of the supratrochlear and supraorbital branches can be done subcutaneously by inserting a tenotome about half an inch external to the line of the latter nerve, and passing it inwards nearly to the root of the nose. In withdrawing it a firm incision must be made along the margin of the orbit, keeping slightly to the frontal side in order to avoid wounding the palpebral ligament, which might be followed by considerable extravasation of blood into the loose tissue of the orbit.

To expose the supraorbital nerve the skin of the forehead must be drawn up and the eyelid down, and a curved incision about three-quarters of an inch in length must be made parallel to the eyebrow and a little below it, the centre of the wound being opposite the notch. The fibres of the orbicularis palpebrarum may then be separated by a blunt instrument, and the nerve exposed as it leaves the orbit lying closely upon the bone. It may then be stretched, or a piece cut out as desired. Care must be taken not to wound the palpebral ligament, otherwise blood may be extravasated into the orbit and suppuration follow.

The Second or Superior Maxillary Branch of the Fifth—This nerve, after crossing the sphenomaxillary fossa, enters a canal in the floor of the orbit, and appears on the face through the infraorbital foramen. The nerve has been divided as it leaves the foramen, in the canal, and in the sphenomaxillary fossa. The situation of the infraorbital foramen is found by drawing a line from the supraorbital notch to the interval between the two bicuspids teeth of the lower jaw. This line crosses the infraorbital foramen, and, if prolonged, will show the position also of the mental foramen. The infraorbital foramen is situated about half an inch below the lower margin of the orbit. The nerve lies rather deeply, but can be stretched subcutaneously in the same way as the supraorbital, by puncturing the skin with a tenotome and grappling for the nerve with a blunt hook, the point of which is made to scrape along the bone below the foramen. When stretching it, the upper lip and cheek must be drawn forcibly downwards. Subcutaneous section can be done in the same situation with a tenotome. To expose the nerve a curved incision, arranged so as to fall into the lines of the face, and about one inch in length should be made with its mid point over the foramen. After dividing the skin the levator labii superioris must be cut

through, and the nerve then comes into view, and when the bleeding has been arrested, can be exposed clearly and stretched or a piece cut out. This operation, however, can be of little use when the teeth are the seat of the neuralgic pain, as the anterior dental nerve is not affected by it. To divide this, it is recommended by Malgaigne to make the incision parallel to the margin of the orbit and immediately below it. A few fibres of the orbicularis palpebrarum are cut through, the origin of the levator labii superioris turned down, and the nerve thus exposed at the foramen. The palpebral ligament is then separated from the margin of the orbit, and pushed upwards with the fat and the eyeball so as to expose the floor of the orbit. The nerve is next cut through as it lies in the canal in the floor of the orbit, with a strong tenotome, which is made to penetrate the antrum, and the terminal branch being seized in a pair of forceps at the infraorbital foramen, it is forcibly dragged out of the canal by which the anterior dental branches are ruptured. The free part is then cut off. This operation is apt to be followed by suppuration in the antrum and orbit. Langenbeck and Hütter have recommended that instead of opening up the orbit, the nerve should be divided subcutaneously just before it enters the canal. To do this a puncture is made in the skin immediately below the outer commissure of the lids, and a blunt tenotome is pushed backwards and downwards till its point is felt to be in the speno-maxillary fissure. The nerve is then pulled forcibly where it has been exposed at the infraorbital foramen, while the tenotome is made to shave along the maxillary border of the fissure. As soon as the trunk is divided, it will pull out of the canal.

Lastly, Bruns, Lücke, Lössen, and others, have exposed and divided the nerve in the speno-maxillary fossa. In order to do this, an incision is commenced just behind the middle of the outer margin of the orbit, and carried downwards to a point opposite the last upper molar. From the upper end of this another is carried backwards to the root of the zygoma. The malar bone and zygoma are cut through, and the arch turned down with the masseter attached. The fat beneath is then pushed back, and, if necessary, some of the fibres of the temporal muscle which are inserted into the posterior part of the coronoid process of the jaw are divided. The posterior part of the superior maxilla is then recognized and followed upwards and backwards to the speno-maxillary fossa. The nerve is then raised with a blunt hook and divided, as large a piece as possible being removed. As the internal maxillary artery and a plexus of veins which lie in the fat may cause troublesome hemorrhage, the dissection should be carried out with a blunt instrument. After the operation the malar bone is replaced and secured by sutures. In some of the cases in which the operation has been performed considerable stiffness of the jaw has been left.

Other methods, also, including partial resection and replacement of the upper jaw, have been recommended.

Third or Inferior Maxillary Division of the Fifth.—The three chief divisions of this nerve, the lingual, inferior dental, and auriculo-temporal, have all been submitted to operative treatment in neuralgia. The *lingual* is easily reached from within the mouth. It runs obliquely forwards to the side of the tongue from a point immediately internal to the last molar tooth. It is covered only by the mucous membrane, and forms a distinct ridge if the tongue be pulled forcibly outwards and to the opposite side. In this situation, the nerve can readily be seized and stretched by means of a blunt hook forced through the mucous membrane, the tongue being forcibly drawn to the opposite side while the nerve is being pulled upon. Section can be made by putting the nerve on the stretch, and passing a curved bistoury to the inner side of it opposite the last molar tooth, and then cutting towards

the jaw. To remove a piece, a longitudinal incision should be made through the mucous membrane in the line of the nerve, which may then be drawn out with a blunt hook.

The *mental branch of the inferior dental* is easily reached, as it emerges from the dental canal. This foramen is situated directly below the interval between the bicuspid teeth. The nerve can be stretched subcutaneously by making a puncture in the skin opposite the first bicuspid at such a level as not to penetrate the mouth. A blunt hook is inserted through this, and forcibly scraped along the bone across the line of the nerve. The lip and chin must be pulled inwards while the nerve is stretched. The nerve may also be exposed, and a piece cut out if desired by a small incision in the same situation.

The *main trunk of the inferior dental nerve* has, in some cases of intense and persistent neuralgia, been divided by dissecting up a flap over the ramus of the lower jaw, applying a trephine to the bone so exposed and cutting out a portion of it over that part where the nerve enters the dental canal, which is thus laid bare; when a portion of the nerve may be excised, by being raised on a director, and snipped away with scissors.

The *Auriculo-temporal Nerve* can be reached only where it crosses the root of the zygoma after emerging from above the parotid gland. It lies immediately behind the temporal artery. In this situation it can be exposed by a small incision parallel to its course, and immediately in front of the tragus, care being taken to avoid the artery. Subcutaneous stretching had better not be attempted for fear of injuring the temporal artery.

The value of these operations is still somewhat doubtful. Many cases of permanent cure have been recorded, and temporary relief lasting for weeks or months very commonly results. No hesitation need therefore be felt in undertaking the less serious proceedings, such as subcutaneous stretching or exposure and division of the terminal branches. The more extensive operations, such as exposing the superior maxillary in the spheno-maxillary fossa, or the inferior dental in the canal, should be reserved for very extreme cases in which all milder proceedings have failed. Wood, of New York, has successfully divided the superior maxillary nerve near the foramen rotundum. In one case of his which I have seen, a complete cure was effected; the patient, a healthy man, being entirely free from the neuralgia one year and a half after the operation.

There is one form of neuralgia of the dental nerves that is so severe and so persistent in its general duration, and so paroxysmal in its attacks, that it constitutes a true *Tic*. This neuralgia may affect either jaw. I have most frequently met with it in the lower, and more commonly in women than in men. It occurs in people who have lost teeth; and the pain, which is excessively acute and paroxysmal, commences in and darts from the contracted alveoli and the condensed and indurated gum covering them. It appears to be owing to the compression of the terminal branches of the dental nerves by the contraction upon them of the empty alveoli. Taking this view of the pathology of this form of neuralgia, I have treated it by the removal of a portion of the indurated alveolar border and gum. Some years ago I did this in a patient of Duméril's, removing a V-shaped piece of the bone by means of a Hey's saw; and more recently, I have in addition clipped away the bone by means of cutting pliers. Gross, who has directed attention to this form of neuralgia, uses the pliers only for the removal of the affected bone. In any case it is necessary to cut into, but not through, the body of the bone. By this incision the dental canal may be opened in the body of the bone, and the nerve destroyed by means of the galvanic cautery.

MUSCULAR TIC.

Muscular tic of the face or "histrionic spasm" consists of almost constant twitching of the muscles of the face, sometimes so severe as to interfere with sleep, and always causing most serious annoyance and discomfort to the patient. During the last few years, the facial nerve has been stretched for relief of this affection in several cases. Godlee has collected thirteen, including two of his own. Of the 13 cases, 6 were unrelieved, the spasm returning as soon as the paralysis caused by the operation passed off: and in 5 the spasms returned, but with less severity; in one only, under the care of Southam, was the cure permanent. One patient was lost sight of. The operation is performed by making a slightly curved incision immediately behind the ear, reaching from the root of the mastoid process to nearly the level of the angle of the jaw. The anterior border of the process and the edge of the tendon of insertion of the sterno-mastoid are carefully cleaned, and the parotid turned forwards. The upper border of the digastric is next found, crossing the wound nearly transversely. The nerve is parallel to this, and according to Godlee it will be found emerging from under the middle of that part of the mastoid process which is exposed in the wound. After the digastric is exposed, the dissection must be carried out with a director and forceps as the deep parts of the wound approach the internal jugular vein. When the nerve is found and cleaned, it must be firmly stretched with two blunt hooks. Complete paralysis of the face should result if sufficient force is used.

In *clonic torticollis* the spinal accessory nerve has been divided in one case by Tilleaux, and stretched by Nicoladoni, at its entrance into the sterno-mastoid. The division gave some relief, but the stretching only exaggerated the spasms.

TRAUMATIC PARALYSIS.

Traumatic paralysis is referable to three distinct sets of causes. First, it may arise from *Injury to, or Compression of the Brain* giving rise to localized paralysis when the cortical motor centres are injured, or to hemiplegia or more general paralysis when the deep centres are implicated, or pressure is exerted on the brain-substance generally. These conditions have already been fully described in the chapter on the Injuries of the Head (pp. 683 and 723, vol. i.). Secondly, it may arise from *Injury of the Spinal Cord*, giving rise primarily or secondarily to lesion of the substance, either by laceration, compression, or ultimate disintegration. The effects produced will vary with the extent and seat of the injury from complete paraplegia, with loss of sensation in the paralyzed parts, to irregular impairment of sensation and motion. (See Wounds of the Spinal Cord, p. 763, and Secondary Effects of Concussion of the Cord, p. 750, vol. i.). Thirdly, *Injury to the Nerves* at any part of their course, from the roots to the terminal subdivisions of their trunks, may occasion paralysis of the parts supplied by them. The effect produced may be immediate, as from Section of a Nerve (see p. 471, vol. i.); or more gradual, from Pressure (see p. 470, vol. i.); or it may occur as the result of Chronic Neuritis following a strain, or other injury (see p. 475, vol. i.).

These conditions having been already fully described, it remains to notice here only a form of paralysis that is occasionally confounded with the traumatic varieties; viz., that arising from exposure to cold, or rheumatic paralysis.

Rheumatic Paralysis, or Paralysis from Exposure to Cold (Duchenne), is a form of disease more frequently spoken about than met with—that is to say, if we apply the term paralysis to loss of nervous power independently of inability to use the limb from muscular weakness, rigidity, or pain, or from similar conditions connected with the joints. Genuine rheumatic paralysis from affection of the nerves does, however, exist. Duchenne states that he has met with it in most of the nerves of the limbs, and it is far from uncommon in the facial nerve. It most commonly arises from exposure of the affected part to a draught or prolonged chill while the body is sweating. It is difficult to assign a distinct pathological cause for it: that it is due to an actual inflammation of the nerve, a neuritis, may be assumed from the symptoms, and the paralysis is probably the result of compression of the fibres of the nerve from edasion into its sheath. The paralysis may arise in two ways. In the first variety there is prolonged evidence of neuritis before the loss of power appears. The first symptoms when a compound nerve is affected is pain along its course, gradually increasing in severity, stabbing or violently aching in character. With this there may be various modifications of sensation in the parts supplied by the nerve, as numbness, tingling, or hyperæsthesia. These symptoms are increased by movement. After lasting some time, even for weeks or months, the pains cease, and the muscles supplied by the nerve become paralyzed, and after a time waste, and then electrical irritability becomes impaired.

In the second variety the preliminary symptoms of neuritis are wanting, the paralysis appearing immediately after exposure to cold. This is commonly observed in the facial nerve, or in the musculospiral and occasionally in other nerves. Duchenne has collected over 100 cases of sudden paralysis of the latter nerve occurring after exposure to cold, usually from sleeping with the arms exposed to a draught. The symptoms of paralysis of the musculospiral have already been described (p. 565, vol. i.) Duchenne states that in paralysis from exposure to cold the whole of the parts supplied by the nerve in the forearm are paralyzed, whereas in wrist-drop from lead palsy the supinator longus escapes. In paralysis occurring in this sudden way from cold the electrical irritability of the muscles remains normal, the facial nerve alone forming an exception to this rule. This is explained by supposing that this nerve is exposed to more severe pressure when it swells, in consequence of its course being through a long canal.

It is important to distinguish these forms of paralysis from that arising from other causes—more particularly from the traumatic forms. This may usually be done by attending to the preliminary history of neuritis in the first form, in which there is also frequently a coexistent or antecedent rheumatic affection of the joints or muscles, and in the second form by the maintenance of the normal irritability of the muscles, remembering, however, that facial paralysis from cold forms an exception to the rule.

The *Treatment* in the early stages is that of neuritis, free counter-irritation and rest, with the administration of salicylic acid if there are any general signs of rheumatism. When paralysis is clearly developed, faradization must be employed to prevent wasting of the muscles. By these means a cure is always effected, although the recovery is often very slow.

NEUROMA.

By **Neuroma** is meant a tumor connected with a nerve. The common neuroma is a fibroma springing from the neurilemma. (See, also, p. 946, vol. i.) It is composed of dense white fibrous tissue, and as a rule the fibres

of the nerve are stretched over it or pass along one side, seldom being involved in the mass.

This tumor may vary from the size of a millet-seed to that of a melon; it is usually solid, but when it attains a large bulk, a cavity may form in it, containing a yellowish or brownish serous-looking fluid, apparently owing to the disintegration of the central portions of the mass. In shape it is usually oval or oblong, the long axis corresponding to the course of the nerve (Fig. 421); it grows slowly, and is movable transversely, but not in the direction of the nervous trunk on which it is seated; it has no appearance of malignancy, and, however large it becomes, it never contracts adhesions to the integument nor involves its structure. Neuroma commonly affects only the nerves of the cerebro-spinal system; but Bérard has met with one case of the disease on a ganglionic nerve. The nerves of special sense are but very rarely the seat of this disease. Indeed, the only recorded case with which I am acquainted of a neuroma connected with one of these nerves, is one described by Lidell, of New York, of a neuroma of the optic nerve filling up the orbit, flattening and protruding the eye, and extirpated, together with the contents of the orbit, by that Surgeon.

Most commonly the tumor is single, and is usually painless. As it increases in size it may become the seat of severe lancinating or neuralgic pain, which extends, however, only to the parts below the tumor, and is commonly paroxysmal. The motor function of the nerve is very seldom affected. The pain is evidently owing to the stretching of the nervous twigs as they pass over the tumor. A single neuroma is sometimes not only painful, but acutely tender when touched; but when many tumors are present it is a singular fact that they are always painless and unattended by any inconvenience except such as arises from their numbers and bulk. The number of such tumors is sometimes amazingly great; thus, in one of R. W. Smith's cases, described in a monograph which contains the fullest and most accurate account of this disease, he counted in the two lower extremities alone more than 250 of these tumors, besides those in other parts of the body. In another case related by him, there were upwards of 200 small neuromata scattered over the sides of the chest and abdomen, 450 on the right lower extremity, and upwards of 300 on the left; altogether probably not less than 2000 of these growths in "this unprecedented case."

Other tumors besides fibromata are occasionally met with in connection with nerves. Myxomata are, perhaps, the most frequent. In 1870 I amputated the leg for a spindle-celled sarcoma of considerable size, which was found on dissection to have sprung from the posterior tibial nerve.

The *painful subcutaneous tubercle* (see p. 947, vol. i.) is probably also a fibroma connected with a nervous twig.

Traumatic Neuromata may arise from the wound or partial division of a nerve. The central end of every divided nerve becomes more or less bulbous, the enlargement being composed partly of dense fibrous tissue and partly of newly formed nerve-fibres. As a rule this condition, which must be regarded as normal, is unattended by any pain or discomfort. Occasionally, however, the enlargement reaches the size of a nut or pigeon's egg, and

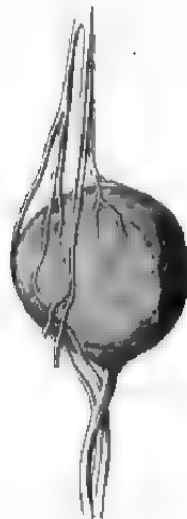

Fig. 421. — Neuroma with Nervous Filaments spread out over Tumor.

the growth must be regarded as a true tumor. It may be acutely painful and give rise to the most intense neuralgic pain.

Treatment.—No neuroma should be interfered with unless it is causing considerable pain by the pain it gives rise to or by its bulk. If it becomes necessary to do something to relieve the patient, excision of the tumor is the most rational mode of treatment. In idiopathic neur-mata the attempt must always be made, by cautious dissection, to remove the tumor from the nerve without cutting that across. This can be done in most cases without difficulty. If it is impossible to save the whole limb, a few fasciculi may be preserved, which will maintain the continuity of the nerve and facilitate subsequent restoration. If complete division is unavoidable, an attempt must be made to suture the divided ends after relaxing the parts as much as possible by position. Even if this fail, restoration of function may sometimes take place.

Traumatic neuromata of stumps are treated by excision.

TETANUS.

Tetanus is a disease consisting essentially in an excited state of the spinal cord and the medulla oblongata—in fact, of the whole true spinal system, giving rise to painful and continued spasms of the voluntary muscles and the involuntary, alternating with incomplete relaxation, and usually terminating fatally.

CAUSES OF TETANUS.—This, which is one of the most serious and distressing diseases to which the nervous system is liable, is in the great majority of instances of **Traumatic** origin, being the consequence of some wound that penetrates or irritates a portion of the peripheral nervous system; the local irritation so produced being propagated to the nervous centres, the excitation of which becomes persistent, and continues after the local cause has been removed, inducing reflex muscular movements in various parts of the body. The irritation of the nervous system, however, that induces tetanus, may arise from other sources besides surgical wounds, occasioning the **Idiopathic** form of the disease; thus, for instance, the presence of worms in the intestinal canal, exposure to cold and wet, the ligature of the umbilical cord in infants, and even the uterine irritation following abortion, have been known to occasion it. These causes, however, rarely give rise to it in this country.

Tetanus may occur at all ages, from the earliest infancy to an advanced period of life. In hot climates it is common amongst newly born infants, in the form of *Trismus Neonatorum*. In this country it rarely occurs at this very early period of life, but is common in young adults. I have most frequently observed it between the ages of 16 and 25, and after that in old people, but it may occur at any period of life. It is far more common amongst males than females—in the proportion of about four to one. Season of the year seems to exercise little influence over it. It occurs in all states of the atmosphere, and at all periods of the year; but is certainly most common when the weather is suddenly changeable—alternating from heat to cold. Indeed, long exposure to cold and wet, more particularly after the body has been heated, is the most common cause of tetanus when it occurs independently of surgical injury, and is a frequent predisposing cause in persons who have been wounded.

Tetanus may be occasioned by injuries that do not give rise to breach of surface—thus I have known it to occur in a child who was suddenly thrown down upon its back by another at play, in a girl from a boy jumping on to and in a lad by another striking him on the back by running a stick at him; and Reid mentions a case produced by the stroke of a

whip; but in the great majority of cases, it is directly occasioned by a *wound* of some kind. Generally a nervous twig has been lacerated, divided, or inflamed; and this seems to have been the starting-point of that disturbance of the spinal system of nerves which leads to the tetanic spasms.

The *kind of wound*, as well as its situation, doubtless influences materially the occurrence of the disease. Though it certainly more frequently follows punctured, torn, and lacerated, than clean-cut wounds, yet it occasionally complicates these, even when they are made in surgical operations; thus, it has been known to follow the removal of the breast, amputation, the ligation of the larger arteries, and the operation for hernia. The minor surgical operations also are not free from the possibility of this dangerous complication. It has been observed after the operation for fistula in ano, the ligation of piles and varicocoele, the removal of nasal polypi; and I have seen a fatal case resulting even from the introduction of an issue. Burns are peculiarly liable to be followed by tetanus. It is the common belief, both in the profession and out of it, that wounds of the hands and feet, and more especially of the ball of the thumb and of the great toe, are more likely to be followed by tetanus than those in other situations. I think the truth of this opinion may be doubted; though it is not improbable that tetanus may occur more frequently after injuries of these regions than of other parts of the body, simply because punctured and lacerated wounds are more common here than elsewhere. It cannot well be supposed to be owing to the tendons and fasciæ that abound here, as Hunter imagined; for it is seldom, if ever, met with after operations for tenotomy, which are so commonly practised on the feet.

The statistics of the American Civil War are very complete on this point. Of 505 cases, 21 followed wounds of the head or neck, 55 of the trunk, 137 of the upper extremity, and 292 of the lower. Of the 137 wounds of the upper limb which were followed by tetanus, all but 4 were above the wrist; and of the 292 of the lower extremity, only 57 were of the foot. These statistics do not therefore justify the popular belief that wounds of the hand and foot are particularly prone to be followed by this affection.

Tetanus may occur in all *constitutions*—in the strong and robust, and in the feeble and emaciated. It is especially apt, however, to occur in feeble and debilitated individuals, and, indeed, may be looked upon as a disease of debility; hence any condition that lowers the tone of the nervous system is especially likely to occasion it. When it occurs in persons who are otherwise strong and in the prime of life, it will be found that they have been exposed to causes of depression influencing the nervous system. It is loss of nervous tone, and not muscular weakness, that disposes to this disease. Thus, in tropical climates, as in some of the West India Islands, and amongst the marches of Cayenne, it occurs with peculiar frequency, the most trifling scratches or punctures being followed by the disease. Polaud, who has exhausted the statistics of tetanus, states that the mortality from it is in London .025, whereas in Bombay it causes 2.5 per cent. of the total deaths. It is interesting to observe, that the natives of hot climates are far more liable to this disease than Europeans resident there. In the American Civil War, 2.1 per cent. of the cases occurred amongst the negro troops, who furnished only 2.7 per cent. of the total number of wounds.

In *military practice* tetanus is of common occurrence. Its frequency varies much in different campaigns and under different circumstances, season, and climate. In the Peninsular War, it was estimated to occur in the proportion of about one case in every 200 wounded; in the Schleswig-Holstein war of 1849, according to Stromeyer, once in about 350 cases. In the Crimea it appears to have been of rare occurrence. Alcock's estimate of one to every 79 wounded is evidently too high. In the American war it occurred in 0.2

per cent. of the wounded. After naval engagements, however, the mortality has often been high, more particularly if they have taken place in tropical climates. Sir G. Blane states that, after Rodney's action in the West Indies, out of 810 wounded 20 were attacked with tetanus, being one in 40. All European Army Surgeons are agreed, that sudden changes from heat to cold are amongst the most frequent causes of tetanus amongst the wounded. Thus Larrey states that, after the battle of Moskowa, although the number of wounded was immense, there were few cases of tetanus, the heat being very great and continuous; whilst after Bautzen, where the wounded were left on the field all night exposed to severe cold, more than 100 had tetanus; and after the battle of Dresden, when great heat was followed by much wet and cold, the wounded suffered most severely. So, after some of the Indian battles, as Chinawallah and Ferozepore, where the wounded lay exposed to cold nights after very hot days (Macleod), tetanus was of very frequent occurrence. The case appears to have been different in America, where tetanus does not seem to have arisen from exposure of the wounded to cold and night-air. Chisholm states that although, from the wooded nature of the country in which the battles were often fought, wounded men were not unfrequently left for two or three days on the ground, tetanus did not appear to be more frequent amongst them than in those immediately cared for. Hennen states that a draught of air, whether hot or cold, directly blowing on the patient, is the most fertile cause of tetanus.

The frequency with which tetanus occurs varies much. It often happens that not one case occurs in a hospital for some years, and then several are met with in close succession or simultaneously.

PERIOD OF OCCURRENCE.—Tetanus may take place at any period after the infliction of the wound that occasions it. In hot climates especially, it may occur very speedily; thus, Robinson relates the case of a negro servant in the West Indies, who scratched his finger with a broken plate, and died of tetanus in a quarter of an hour. It is very seldom, however, in temperate climates, that it supervenes before the fourth or fifth day, usually from that to the tenth day. Larrey, who had great experience of this disease, during Napoleon's campaigns in Egypt, met with it most frequently between the fifth and fifteenth days after the infliction of the wound. According to the experience of the Surgeons of the Peninsular War, under whose observation many hundred cases came, the disease does not show itself after the twenty-second day; but, though this may be the general rule, Sir G. Blane has related a case in which it took place as late as a month after the infliction of the wound. It is stated that it may take place after the cicatrization of a wound is completed; when this happens, the disease must rather be looked upon as being idiopathic, accidentally occurring in a person who has been recently injured.

In the American War out of 367 cases in which the day of appearance of the disease is noted, it followed secondary amputations in twenty-one cases during the first day after the operation; and in six it appeared in the first twenty-four hours after the original wound. After this but few cases appeared till the fifth day, when 19 are recorded. The highest number was 31, on the eighth day, and by the fifteenth day the number fell to 6. Seven cases occurred between the 26th and 30th days, and 23 after the end of the month.

FORMS.—Tetanus may be *Acute* or *Chronic*, being in some instances fatal in the course of a few hours, but usually lasting for three or four days. Poland states that at Guy's 50 per cent. of the cases were fatal before the fifth day after division. In the American War, out of 368 cases, 1 recovered and 69 died during the first day; 1 recovered and 85 died on the second day; 49 died on the third, 31 on the fourth, 22 on the fifth, 19 on the sixth,

and 14 on the seventh, and 7 on the eighth day. Thus of the acute cases 2, evidently slight in character, recovered, and 294 died before the end of the eighth day, and in 203, or more than half, the disease did not exceed three days in duration. From the ninth to the nineteenth day inclusive, 36 died and 6 recovered; from the twentieth to the twenty-seventh inclusive, 7 died and 7 recovered, and 6 survived beyond the twenty-seventh day and finally recovered. The longest period during which the disease lasted was forty-nine days. These interesting statistics confirm the view that the more chronic the disease becomes the better is the chance of recovery; indeed, if the patient survive the tenth day, the prospect of a favorable issue to the case is materially increased. As a general rule, those cases are the most fatal which are most active in their symptoms; danger being in the ratio of the acuteness of the attack, both as to severity and also as to rapidity of invasion after injury.

SYMPTOMS.—The invasion of the disease is sometimes preceded by a general uneasiness on the part of the patient, a feeling of illness or weakness, or a sense of impending mischief. Abernethy was of opinion that tetanus was usually ushered in by a disturbed state of the digestive organs, the stools being offensive and indicative of much gastric irritation. When the disease sets in gradually, it may be somewhat difficult of recognition in its early stages; if it come on suddenly, its nature is immediately evident. It is a remarkable fact that the cramps do not begin in the part injured; but, wherever this may be situated, they are always first noticed in the muscles of mastication, of the face, and upper part of the neck; and, throughout, these and the muscles of respiration are principally affected. In tetanus, the circle of nervous disturbance is at first very limited. It is confined to the muscles supplied by the motor branch of the fifth, by the portio dura of the seventh, and by the spinal accessory. These nerves appear to be alone affected; the sensory division of the fifth is never influenced throughout the disease. The spasm may be confined to the muscles supplied by these nerves, as is the case in trismus; but it soon spreads to the true spinal nerves, being, however, confined to their motor divisions. The first symptoms usually consist in the patient feeling a stiffness or soreness about the jaws and throat, being unable to open his mouth widely, to take food or drink, the muscles about the temples, jaw, and neck feeling stiff and rigid; this condition has given to the disease the popular term of *lock-jaw*. As the affection advances, the countenance assumes a peculiar expression of pain and anguish, the features are fixed or convulsed from time to time, and the angles of the mouth drawn up, constituting the appearance called *risus sardonius*. When fairly set in, the disease is marked by spasms of the voluntary muscles of the most violent character, with much pain and only partial remissions. The pain is of that kind that attends ordinary cramp in the muscles, as of the legs, and is usually very severe. The spasms are often jerking, the patient being suddenly thrown up or twisted on one side; the breath is drawn with a loud sobbing catch from spasm of the diaphragm, and from the same cause there is usually violent pain experienced in the epigastric region, darting across to the spine. The muscles of the trunk are usually affected next in order of frequency to those of the head and neck, the body being bent backwards so as to form a complete arch (*Opiethotonos*); more rarely it is drawn forwards (*Emproethotonos*); and still less frequently to one side (*Pleuroethotonos*). In some cases the body becomes perfectly rigid, like a piece of wood, the belly being drawn in, and the chest expanded. It is said that in severe cases the spasms have been so violent that muscles have been ruptured, teeth broken, and the tongue lacerated. In the numerous cases of tetanus that I have unfortunately witnessed, it has rarely fallen

to my lot to see any effects of this kind produced; the spasms, indeed, being in general not very violent, though continuous and very painful. The only muscles that I have seen torn have been the recti of the abdomen.

The intellectual faculties are not disturbed, and the mind continues clear to the last. Cases of tetanus occasionally prove fatal without any elevation of temperature; but in most instances there are great heat of surface, profuse sweats, and quickness of pulse; not so much from any febrile disturbance, but apparently from the violence of the muscular contractions. In most cases this symptom is peculiarly marked, especially towards the end of the case, when the temperature may rapidly rise to extraordinary heights. Thus, Wunderlich has recorded a case in which it reached 112.55° Fahr. immediately before death. It may rise a few tenths of a degree higher after death in these cases. The prolongation of life appears to depend greatly upon the intensity of the convulsive movements: the more severe these are, the sooner does death result. The fatal termination occurs not so much from any great physical lesion, or disturbance of important parts, as from exhaustion consequent on the frequency of the tetanic spasms.

PATHOLOGY.—There is surely nothing more remarkable in the whole history of disease than that, in consequence of a trivial wound inflicted on a distant part of one of the extremities of the body, an otherwise apparently healthy man should be seized with a spasmodic affection of the muscles of the jaws; that this spasm should extend to the trunk; and that after a few hours it should be followed by general convulsive movements which will, in the great majority of instances, speedily end in death. It might reasonably be expected that such a train of phenomena would leave the most unmistakable evidences of the conditions that had given rise to them, and that pathological anatomy would at once, and in the clearest manner, enable us to unravel the mysterious bonds that connect a graze of the foot with a spasm of the muscles of the neck and jaw. But in this we shall be grievously disappointed, for the morbid appearances found after death from tetanus throw but little light on the real nature of this affection,—so little, indeed, that it has been frequently described as a "functional disease." But in saying that this or any other disease is functional, we express only our ignorance of its real cause. There is no function without an organ to perform it; and there can be no derangement of a function without a corresponding and concomitant disorder of the organ that produces it. Every "functional" disease must, therefore, at last be referred to an organic lesion. The term "functional" is employed only when we are not acquainted with the true nature of the disease. As less is known of the real physiology and pathology of the brain and spinal cord than of other organs of the body, we have more "functional" diseases of the nervous system than of the circulatory or respiratory. But, as pathological anatomy becomes more studied, and as minute investigations into structure are entered upon, so the class of so-called "functional" diseases becomes narrower. We do not speak of "functional" coma, because we can appreciate the different conditions that occasion compression of the brain; but we still sometimes speak of functional convulsive diseases and of functional amaurosis. The ophthalmoscope, however, has shown that "functional" amaurosis does not exist, but that the failure of visual power is always dependent on some change of structure in the interior of the eye, and advances in pathology will doubtless show that other so-called functional diseases of the nervous system are in reality dependent on structural lesions.

State of the Nerves at the Seat of Injury.—There is one morbid condition that will, I think, invariably be found in tetanus, viz. a marked congestion and inflammation of the nerve connected with, and leading from,

the wound that has occasioned the disease. This morbid state I have never found wanting. In all cases of fatal tetanus that I have seen in which a careful dissection has been made, the signs of inflammation of a nerve communicating with the wound have been found; and the vascularity, which is often very intense, may be traced up the neurilemma, often to a considerable distance. In a case of tetanus following a wound of the knee, in a patient who died in University College Hospital, a small branch of the internal cutaneous nerve was found to have been injured, and was inflamed. In another patient who died of tetanus about sixteen days after treading on a rusty nail, a black speck was found on the internal plantar nerve, where it had been wounded by the nail. In a man who died of acute tetanus a week after receiving a lacerated wound of the dorsum of the foot, the digital nerves were found to be sloughy, and evidences of inflammatory irritation extended some distance up the musculo-cutaneous nerve. In another case under my care, in which tetanus resulted from a bruise of the back, and terminated in death, the injured nerve (a dorsal branch) was found lying bare and reddened in the wound; and, on tracing it up to the spinal cord, its sheath was found to be much injured and ecchymosed. In another instance, in which tetanus followed a wound of the wrist, the external cutaneous nerve was found in a similar inflamed state.

The Pathological Conditions found in the Spinal Cord in cases of tetanus have been studied by Rokitsky, Lockhart Clarke, Dickinson, and Allbutt. Rokitsky described them as consisting chiefly of a proliferous development of connective tissue, composed of young cells. Billroth doubts the correctness of this observation; and many competent observers have failed to discover anything more positive than ecchymosed patches and interspaces in the spinal medulla. Lockhart Clarke has in at least six cases observed lesions of structure in the spinal cord, consisting of disintegration and softening of a portion of the gray substance of the cord, which appeared in certain parts to be in a state of solution. The fluid thus formed was in some parts granular, holding in suspension the fragments and particles of the disintegrated tissue, but in many places it was perfectly pellucid. He considers this due to hyperæmia of the cord, accompanied by exudation and disintegration. Dickinson has described intense hyperæmia with a structureless exudation poured out around the vessels in many parts of the gray matter, breaking down the surrounding tissue. He observed also some hemorrhages in the white columns. These observations have been confirmed by Clifford Allbutt, but the exact significance of the changes observed is still uncertain.

The absence of any constant and distinct pathological lesion has led to the hypothesis of tetanus being dependent primarily on blood-poisoning, and not on a lesion of the nerve-centres. Billroth, who inclines to this idea, admits that it is a mere hypothesis. This theory of blood-poisoning being the primary cause of tetanus is based on the following line of argument. A chemical substance, capable of producing convulsive movements when it is absorbed into the blood by its action on the nervous centres—of acting, in fact, like strychnia—may be supposed to be generated in certain circumstances, whether due to some individual predisposition, or to some peculiar fermentative process in the discharges of the wound or at the seat of injury. We have the analogy of hydrophobia in support of the idea that, in certain circumstances, such an agent may be generated in the system, rendering the fluids—blood and saliva—poisonous to others, and capable of developing a convulsive disease in the animal affected. We have, however, no evidence as yet that the blood or any one of the secretions of a tetanic patient is capable, when inoculated, of producing a similar disease in a healthy animal.

There is one objection to this theory which appears to me too serious to

be overlooked, viz., that tetanus has been arrested, if not cured, by the division of the principal nervous trunk leading from the seat of injury, as the posterior tibial nerve in cases of tetanus arising from wound of the sole of the foot. This fact appears to me to point rather to a primary nervous lesion than to blood-poisoning as the exciting cause of the tetanic convulsions.

TREATMENT.—The treatment of tetanus is of a local and of a constitutional character. The **Local Treatment** has for its object the removal of the irritation that has induced the tetanic condition. It is true that, when once tetanic excitement has been set up in the cord, it has a tendency to continue, and to be incapable of removal by the mere abstraction or cessation of the local irritation which gave rise to it in the first instance. It is, however, only reasonable to suppose that other treatment will succeed best if local irritation be removed; and, indeed, so long as this continues to keep up the centric nervous disturbance, no general means can be expected to succeed; as they will have not only to combat already existing disease, but also to overcome the continuous excitement maintained by the local disturbance. Hence it is of importance to bring the wound into as healthy a state as possible, and to see that it is clean, free from foreign bodies, and not inflamed. In order effectually to remove all local disturbance, recourse has been had to amputation; but though this may have succeeded in checking some of the more chronic forms of the disease, yet other and milder local means have sufficed equally well, and in the majority of cases it has had no effect, and hence so severe an operation can scarcely be recommended for adoption. The division of the trunk of the injured nerve, at some distance above the wound, if there be one that has been punctured or lacerated, has occasionally proved successful. Thus, in a case of tetanus following injury of the supra-orbital nerve, Larrey cut this across, and the patient recovered. In a midshipman, in whom tetanus came on the day after the sole of the foot had been wounded by treading on a rusty nail, Murray divided the posterior tibial nerve, and the patient got well. In those cases in which no special nerve appears to have been injured, Liston's recommendation of making a Λ -shaped incision down to the bone, and above the part, so as to insulate it completely, may be advantageously followed. After the nerve has been divided, or the part properly insulated, some solution of atropine may be carefully applied to it, so as still further to lessen local irritation. Instead of dividing the nerve leading from the source of irritation, it has been suggested that the operation of stretching should be performed. This has been done in a considerable number of cases, and as with every other of the scores of remedies, local and constitutional, that have been recommended for tetanus, recoveries have taken place after its employment. On the other hand, in acute cases it has proved as impotent as the rest.

In the **Constitutional Treatment** of the disease, it is necessary to bear in mind that tetanus is an affection of debility, the violence of the spasmodic paroxysms giving an appearance of false strength to the patient; and that the principal source of danger and death is the exhaustion induced by the energy of the muscular movements. The means adopted should, therefore, have for their object the removal of irritation and the support of the patient's strength, so as to enable him to hold up against the disease.

Nothing can be more unsatisfactory than the treatment of the *Acute* form of traumatic tetanus. In it, all medicines are useless as curative agents. But, though medicines are of no avail as means of cure, they may act as palliatives, and afford relief to the patient; and much may be done by the Surgeon, by removing all sources of external irritation, to mitigate his sufferings, and to place him in a favorable condition to withstand the exhaustion, and to lessen the torture of the spasms. With this view, the first thing to

be done is to clear the bowels out well with an aperient dose; aided, if necessary, by a turpentine enema. The patient should then be kept perfectly quiet in a room by himself, a screen or muslin curtains, as recommended by Marshall Hall, being drawn round the bed, as noise or movement of any kind increases the spasms greatly. In order to allay the spinal irritation, the most effectual means consists, perhaps, in the plan recommended by Todd, of applying ice along the whole length of the spine; this is best done by a caoutchouc spine-bag. This is a powerful depressing agent, and, unless care be taken, may lower the heart's action too much, or, indeed, completely extinguish it. It may, however, be applied with safety for six or eight hours, the condition of the patient being looked to in the meanwhile. Sedative or antispasmodic agents are of no use whatever in acute traumatic tetanus. I have seen many drugs of this kind employed without producing any effect in lessening the violence of the convulsions. In most cases, however, the inhalation of chloroform, or the administration of chloral, materially lessens their severity, and gives the patient at least temporary ease.

In the *Subacute* or *Chronic* form of the disease, recovery is much more likely to take place; and it is only in these cases that antispasmodics and sedatives have been of use, and in these also chloroform and chloral are far more beneficial than in the acute cases. There is a kind of trismus occurring in females, often of a hysterical nature, which is at once removed by the inhalation of chloroform. Almost every drug in the pharmacopœia of a tonic, sedative, or antispasmodic nature, has been employed in tetanus; and the recovery which has occasionally resulted has been perhaps overhastily attributed to the remedy, rather than to the employment of those dietetic and hygienic means which are of the first importance, by enabling the patient to live on until the disease wears itself out. Tonics, especially iron and quinine, have been employed by some. Elliotson was strongly impressed with the value of the carbonate of iron. Sedatives in all forms—conium, belladonna, opium, and their alkaloids—have been largely and most ineffectually employed. Miller speaks highly of *cannabis indica* pushed to narcotism, three grains of the extract, or thirty minims of the tincture, being given every half-hour or hour; and Haughton has employed nicotine in one-drop doses, administered every second hour, with complete success in severe cases of traumatic tetanus.

The Calabar bean (*Physostigma*) is the remedy that, perhaps, deserves physiologically the most attention; for as it is nearly, if not quite, antagonistic to the tetanic spasms of strychnia, it was hoped that it would be found equally useful as a sedative to the spinal cord in those arising from traumatic causes. In E. Watson's hands, very successful results followed its administration. Yet it is far from being a specific. I have tried it in several cases, with no appreciable good effect. It may be given by the mouth, hypodermically, or *per anum*; in the form of a solution or a tincture of the extract in half-grain doses, by the mouth; hypodermically, in doses of one-sixth of a grain; *per anum*, in grain doses. The dose should be given at least every second hour, until complete contraction of the pupil occurs. Stimulants, as brandy, should at the same time be given to counteract the depression that will result from the use of the drug. At the same time that recourse is had to such measures as these, it must not be forgotten that the disease is one of great exhaustion and that the patient will die worn out, unless he be supplied with plenty of nourishment. Beef-tea and wine should, therefore, be administered by the mouth, as long as the patient can swallow, and nutritious enemata by the rectum; and in this way the powers of life may be supported until the violence of the disease expends itself. I am, however, disposed to

think that even in these chronic cases, much more may be done by simple than by specific treatment. Clearing out the bowels by a turpentine enema, breaking the violence of the spasms and giving the patient rest and ease by chloroform inhalations or by chloral enemata, and keeping up the powers of the system by injections of beef-tea, egg, and brandy into the rectum, till the disease wears itself out, appear most likely to be followed by a satisfactory result, when used in addition to the hygienic measures recommended in the acute form of the disease. It is certainly more rational to employ such measures as these, than in the vain hope of finding a specific for tetanus, to be constantly recurring to antispasmodic and sedatives, which repeated experience has proved to be useless as curative agents.

CHAPTER XXXIX.

DISEASES OF THE LYMPHATIC SYSTEM

INFLAMMATION OF THE LYMPHATIC VESSELS.

Lymphangitis, or, as it was formerly called, **Angeioleucitis**, is a diffuse inflammation of the lymphatic vessels.

CAUSES.—In the vast majority of cases it arises from the irritation caused by the presence within the vessels of the products of an infective inflammation affecting the tissues from which they derive their lymph. It thus forms rather a complication of these inflammations than an independent disease. Most commonly it is associated with cutaneous erysipelas, but it is also met with in other forms of infective inflammation; thus it is a frequent result of the inoculation of virulent matter from dead bodies, and is occasionally seen in the lymphatics leading from a soft chancre. In most cases, therefore, a wound or abrasion serves as the starting point of the inflammation. It is very rarely, indeed, that lymphangitis occurs without some such external cause; yet we are certainly warranted in considering it as of idiopathic origin in some instances. I have at least seen cases in which careful examination has failed in detecting any breach of surface or evidence of local infection. The disease is predisposed to by the same causes that favor the development of erysipelas, as by atmospheric vicissitudes, by particular seasons of the year, more especially the early spring, and by epidemic influences. Broken health and the neglect of hygienic precautions also tend to induce it.

MORBID ANATOMY.—The walls of the inflamed vessels become swollen, softened, and infiltrated with small round cells, and the endothelium desquamates. Tessier states that the lymph coagulates, forming a rosy clot which plugs the vessel. The inflammation, though commencing from irritation within the vessel, soon extends beyond its walls, the surrounding areolar tissue becomes swollen and infiltrated with inflammatory products, and sometimes suppuration may take place around the inflamed lymphatic.

SYMPTOMS.—During the progress of an ordinary injury, the patient is seized with chills or rigors, with considerable elevation of temperature reaching 102° F. or 103° F., attended, perhaps, by vomiting or diarrhoea. These symptoms may precede by twelve or fourteen hours the local signs of the dis-

case, but more commonly accompany them. On examining the part it will, if superficial, be seen to be covered by a number of fine red streaks, at first scattered, but gradually approximating to one another so as to form a distinct band, about an inch in breadth, running from the part affected along the inside of the limb to the neighboring lymphatic glands, which will be felt to be enlarged and tender. The band itself feels somewhat doughy and thickened. Sometimes one lymphatic can be felt hard and isolated like a piece of whip-cord. There is usually more or less cedema of the limb, from the implication of the deeper lymphatic vessels and their obstruction by the inflammation. Along the course of the inflamed lymphatics, erysipelatous-looking patches not unfrequently appear, and coalesce until they assume a considerable size, and constitute a distinct variety as it were of erysipelas. In some cases the glands are affected before any other local signs manifest themselves, owing probably to the deeper seated lymphatics having been first implicated; or possibly to the direct absorption of and deposit in them of some infective matter that constitutes the primary source of the inflammation. Not uncommonly throughout the disease the inflammation continues to be confined principally to this set of vessels, giving rise to great and brawny swelling of the limb, but without much if any superficial redness. The constitutional disturbance, at first of the active inflammatory type, may gradually subside into the asthenic form.

RESULTS.—The disease usually terminates in resolution at the end of eight or ten days; not uncommonly it runs on to erysipelas; and in other cases, again, localized suppuration may take place, sometimes in the form of one large deep-seated abscess in the iliac fossa or in the thigh if the lower extremity, or under the pectorals and in the axilla if the upper extremity be the seat of irritation; or a chain of abscesses may form along the course of the inflamed lymphatics and in the glands to which they lead. In some instances, after the disappearance of the disease, a state of chronic and rather solid cedema of the part may be left, giving rise indeed to a species of false hypertrophy, and constituting a troublesome consequence. More rarely death results, either from general blood-poisoning, or as the effect of exhaustion from prolonged suppuration of deep-seated abscesses.

The **DIAGNOSIS** of inflammation of the lymphatics has to be made in its early stages from phlebitis and erysipelas, and of the abscesses in later stages from those of pyæmia. From phlebitis it is easily distinguished by the superficial redness of lymphangitis, and the absence of the cord-like plugged vein. From erysipelas it is distinguished by the want of a defined margin to the redness, and by its extending in the line of the lymphatic vessels only; but the affection in most cases is closely allied to erysipelas, and in others merges into it, and consequently the distinction is often of little consequence. The acute lymphatic abscess is usually distinguished without difficulty from the pyæmic; the lymphatic abscess being, if deep, solitary; if superficial and multiple, confined to the tract of the previously inflamed absorbents; in either case being always between the starting-point of the primary source of irritation, or wound, and the glands; in the calf, thigh, or iliac fossa, if the primary irritation be in the lower extremity, in the axilla if in the upper. The fever is moreover more continued, and the severe rigors and sweatings of pyæmia are wanting.

TREATMENT.—In superficial lymphatic inflammation of the skin and integumental structures, the local application of belladonna, as recommended by C. Heath, is the most efficient agent in subduing the local process; a paste of equal parts of the extract and of glycerine should be thickly smeared over all the inflamed parts, and covered with a thick layer of cotton-wool; the limb at the same time being kept elevated. As a substitute treatment,

though of inferior value, hot poppy-fomentations may be used. If after the subsiding of the acute inflammation much chronic induration and oedema occur, bandaging, so as to compress the limb, and methodical friction will be of service. If abscesses form, they should be opened early and treated on ordinary principles.

The constitutional treatment is the same as for erysipelas. No depletion is ever justifiable, and stimulants are often required in considerable quantities, with abundant liquid food of a nourishing kind. Perchloride of iron and quinine are often useful.

VARIX OF THE LYMPHATIC VESSELS.

Varix of the Lymphatics has been occasionally met with, both in the superficial and deep networks and in the lymphatic trunks. The part most commonly found affected has been the inner side of the thigh; but the disease has been seen also in the anterior wall of the abdomen, about the ankle and elbow-joints, and on the prepuce. In the superficial lymphatics, the varix first appears in the form of small elevations, giving the skin an appearance which has been compared to the rind of an orange; it subsequently takes the form of little vesicles covered with a thin layer of epidermis. Varix of the larger lymphatic trunks frequently accompanies the condition just described. The vessels may either be dilated cylindrically into round beaded enlargements, often semi-transparent, and but slightly compressible, or ampullæ may be formed on them, giving rise to more or less soft swellings, fluctuating under the finger. There is some oedema, attributable either to obstruction of the lymphatics or to the impeded flow of the lymph.

In 31 out of 55 recorded cases, a discharge of lymph (**Lymphorrhœa**) has been observed. This has been seen to occur also without varix, as the result of wound. In the latter case the flow is continuous; while in the lymphorrhœa which attends varix, it is to some extent intermittent. The identity of the fluid discharged with lymph has been established by chemical and microscopic examination. An excessive discharge of the fluid is liable to produce symptoms of general debility, of the same kind as those induced by hemorrhage.

TREATMENT.—Spontaneous cure of lymphatic varix has been observed in cases where the penis was affected, the disease being the result of the obstruction to the flow of lymph caused by buboes. In other instances, various plans of treatment have been tried, with apparently indifferent result. Caustics have been used by several Surgeons, but, as the disease is often deeply seated as well as superficial, with but little result. Beau treated three cases successfully by introducing a seton into the dilated lymphatic vessels, and exciting adhesive inflammation. B. Bell advises ligature of the lymphatic vessel from which the discharge of fluid takes place. Compression by means of a bandage has been recommended by Nelaton.

ELIPHTANTIASIS OF THE LEGS AND SCROTUM.

Elephantiasis Arabum, or, as it is often called, the **Barbadoes Leg**, is an affection that is common in many tropical countries, in the West Indian Islands and in South America more particularly. It is met with, though comparatively rarely, in Europe. The disease usually affects one of the lower extremities, seldom both, the scrotum, or the labia, which may become enormously enlarged and hypertrophied. In the face it is often met with in the upper extremities rarely.

It is not my intention to enter into an account of the history, the symptoms,

or the causes of this remarkable malady. It is sufficient for my purpose here to say, that it appears to consist in disease primarily seated in the lymphatics. The glands, as Virchow and Rindfleisch suppose, become impervious to the transmission of lymph, and the hyperplastic deposits that characterize the disease are, together with the general stretching and hypertrophy of the integumental structure, the consequence of the plastic effusion into the areolar tissue.

TREATMENT.—When this disease attacks the face, little, if anything, avails in the way of treatment. When it affects the labia and scrotum, the

Fig. 422.—West Indian Elephantiasis.

enlarged and diseased part must be removed (see Diseases of Penis and Scrotum). But when the leg is affected, surgery can effect much in the way of cure. In the slighter cases much may be done by elevation of the limb, methodical bandaging, and perhaps, as Rayer and Lisfranc recommend, the employment of scarification. But in the more severe cases, where the limb has swollen to a monstrous size, and has become shapeless from the groin to the ankle, the skin sallow, covered with nodules and overlaid by branny desquamation, with a tendency to unhealthy and incurable ulcerations—in these advanced and serious cases, more active measures are necessary.

Dufour seems to have been the first to propose diminution of the supply of arterial blood to the limb as a cure for this disease. This he effected by compressing the femoral artery by means of a kind of truss, and was successful in four cases. This practice of compression has since been successfully followed by Hill, Cockle, Vanzetti, and others.

To Carnochan is due the merit of having recommended the ligature of the femoral artery as a means of cure in these cases; and, in whatever way it acts, there can be no doubt of the excellent effects that have followed this method of treatment, little as it can be explained by the received pathologi-

cal views of the disease. In some instances, as by Bryant, Buchanan, and Simon of Heidelberg, the external iliac has been advantageously tied. The operation on this artery has the recommendation not only of being completely above the limits of the disease, and consequently in parts that are quite healthy, but also of more completely controlling the nutrition of the limb than can be done by ligature of the superficial femoral.

Eppner, in 1881, collected the records of 49 cases of elephantiasis treated by ligature of the main artery leading to the diseased part. In 40 of these the femoral was tied; in 5, the external iliac; in 2, the popliteal; in 1, the anterior tibial; and in 1, the brachial. Of these 31 are reported to have been cured, 3 relieved, 1 unrelieved, and 5 died. Of the cases reported as cured 9 subsequently relapsed. The result of the operations appears to have been fairly encouraging, although in a certain number of cases it is evident that little, if any, improvement took place.

LYMPHADENITIS, OR INFLAMMATION OF THE LYMPHATIC GLANDS.

Acute Inflammation of the Lymphatic Glands almost invariably results from the irritation of some noxious material conveyed to them by the lymphatic vessels. The lymphatics through which it passes on its way to the glands may themselves be inflamed, but more frequently they escape. This fact would seem to indicate that in the majority of cases the irritating matter is particulate and not in solution; as we know from experiment that solid particles pass readily through the lymphatic vessels without lodging, but are arrested in the lymphatic glands. In every acute inflammation the quantity of lymph passing through the glands in connection with the affected area is greatly increased. In simple inflammations in a healthy subject this causes slight swelling, which subsides as soon as the cause is removed; but in scrofulous subjects, as before pointed out, there is a peculiar tendency to inflammation of the lymphatic glands from slight causes, and in them the swelling may persist, and may pass on to suppuration or chronic inflammation. In infective inflammations the inflammatory products contain the special virus to which the inflammation is due, and this being carried by the lymph-stream to the glands may excite a similar process in them. Many specific inflammations are accompanied by the presence of microscopic organisms of a definite form in the exudations, and in such cases the organisms can frequently be demonstrated by the microscope after death in the lymphatic glands nearest to the seat of the disease. As a rule, the secondary inflammation in the glands closely resembles in character that at the primary seat of disease.

Thus, in cutaneous erysipelas, the glands are invariably swollen and tender, but seldom suppurate; in soft chancres, suppuration commonly takes place; and in diphtheria, the glands are always enlarged and painful, but pus rarely forms, while in scarlet fever suppuration is often very troublesome. In syphilis, the change that takes place in the lymphatic glands is identical with that occurring at the seat of inoculation; and the same is the case in secondary tuberculosis.

Some infective inflammations, as hospital gangrene and phlegmonous erysipelas, have but little tendency to infect the glands. This is possibly due to coagulation of the lymph in the spaces of the inflamed area.

In the majority of cases there is no difficulty in discovering the source of the irritation which has caused the glands to inflame. In scrofulous subjects, however, the effect may be produced by causes so comparatively slight that their detection becomes proportionally difficult. In some cases it appears to arise simply in consequence of a strain, as in overwalking. In children, the

glands are more prone to suppurate from slight sources of irritation during convalescence from measles or some other acute specific disease.

Pathological Anatomy.—Inflammation of the lymphatic glands may be acute, subacute, or chronic. In the acute form the gland is swollen, and at first pink in color and soft. At a later stage yellow points of commencing suppuration will be observed, both in the medullary and cortical part. At a still later period the greater part of the gland may be hollowed out into a cavity filled with pus. The appearances of subacute inflammation are much the same as in the acute. The microscope shows the usual changes observed in all inflammations; the vessels are distended, and the gland is crowded everywhere with multitudes of small round cells. These very early choke the lymph-sinuses. As these cells exactly resemble the normal corpuscles of the gland, it is impossible to determine whether they are formed by multiplication of the normal lymphoid cells, or have been brought to the gland with the lymph from the inflamed area, or have migrated from the vessels. The capsule and trabeculae are similarly infiltrated with small cells. The formation of pus takes place in the same way as in other parts. In the less acute forms larger cells are found, formed by proliferation of the flattened corpuscles that cover the trabeculae and the inner aspect of the capsule. In the more acute forms the surrounding tissues are early implicated in the inflammation.

Chronic Inflammation of the Lymphatic Glands is regarded as the most characteristic feature of scrofula. In it the gland is enlarged often to many times its normal size. In the early stages, it is usually more opaque than natural, and of a gray or dull pink color. At a later period, yellow points appear, due to caseation. These points gradually increase in size, and coalesce till the whole gland becomes a uniform caseous mass still enclosed in the capsule, which is often considerably thickened. The caseation may terminate the process, the cheesy mass remaining dry and encapsuled without further change. In other cases it is followed by deposit of lime salts, and the diseased gland forms a hard calcareous mass. These formations most commonly occur in the glands of the abdomen and thorax. In superficial glands the caseation is more commonly followed by softening of the cheesy mass, which breaks down into a thick fluid not unlike clotted cream. The softening is accompanied by inflammation, and the slow formation of pus in the tissues round the gland, the capsule gives way at the most superficial part, and the fluid gradually approaches the surface. The chronic abscess thus formed is very slow in perforating the skin, often undermining it for some distance before finding an exit. Microscopic examination of these glands shows in the early stages a great increase in the lymphoid corpuscles, not only in the follicles of the gland, but also choking the lymph-sinuses. Amongst the new corpuscles larger cells are found many times the size of a lymph-corpuscle, and apparently developed from them, as all intermediate varieties are found between the two forms. The flattened cells covering the trabeculae, and lying on the meshes of the reticulum of the gland, proliferate, and may sometimes be recognized forming a coarse network amongst the lymphoid corpuscles. At first the gland is more vascular than natural, but from the pressure of the accumulated cells the vessels soon become obliterated, and non-vascular areas are formed. At this stage, in a very large proportion of scrofulous glands, giant-cells surrounded by a zone of larger cells, and again by lymphoid corpuscles, forming thus the anatomical structure of a tubercle nodule, are met with in the non-vascular patches. The caseation commences in the non-vascular spots, and gradually extends. The trabeculae disappear last in the caseating process. In a large proportion of cases examined up to the present time, the tubercle bacillus has been found in the cheesy glands.

In the present state of our knowledge, it is not possible to define accurately the relation of tubercle to chronic glandular inflammation. In those cases in which the glandular disease is secondary to a tubercular affection of the region from which they receive their lymph, they are probably tubercular from the beginning. In other cases the chronic inflammation may be antecedent to and a predisposing cause of the development of tubercle; and again it is probable that chronic inflammation followed by caseation and softening may take place without the process being at any time tubercular. The softened caseous product of chronic inflammation of the lymphatic glands has been believed for many years to be a source of general tubercular infection, the fine granular debris entering the circulation and lodging in distant parts, and there causing the growth of tubercle. Since Koch's discovery of the bacillus of tubercle, this organism has been believed to be the actual infective material in such cases. This general infection when it does occur is, however, merely an accidental occurrence, the vast majority of patients who suffer from caseating lymphatic glands escaping with nothing more than the local disease.

Induration of the gland, due to thickening of the trabeculae and capsule and of the meshes of the retiform connective tissue, is not an uncommon result of slight degrees of chronic inflammation.

In whatever way occurring, inflammation of the lymphatic glands always causes obstruction to the flow of lymph through them, and if the whole or greater part of the glands of a limb be affected, oedema, often of a solid character, may occur in the parts from which they receive their afferent lymphatic vessels.

SYMPTOMS.—In **Acute Lymphadenitis** there are pain, swelling, tenderness, and stiffness about the affected glands, with a dull heavy sensation in them. The outline of the swollen gland is at first clearly defined, but soon becomes concealed by the inflammation extending to the contiguous areolar tissue. Before long redness, oedema, and the other signs of acute abscess make their appearance. In **Subacute Lymphadenitis** the glands become swollen, enlarged, and tender, and are matted together by inflammatory exudation into the surrounding tissues. If abscess form, it frequently commences in the structures around the glands; and those are, perhaps, eventually exposed at the bottom of the cavity that results. This is especially apt to happen in cachectic and strumous persons from slight sources of irritation. Very commonly in such subjects the inflammation of the glands runs into a chronic state. **Chronic Lymphadenitis or Strumous Enlargement of the Lymphatic Glands** may arise as a sequence of subacute inflammation, but more commonly the glands gradually enlarge without marked pain or tenderness in consequence of chronic irritation of some kind. It is not possible to make any accurate distinction clinically between simple chronic inflammation, strumous enlargement, and tubercular disease. Chronic inflammation of the glands is commonly looked upon as the most marked characteristic of the strumous diathesis, and the relation of the process to tubercle has been already sufficiently discussed. These changes occur principally in children and young people, and most frequently in the neck, especially in the submaxillary glands and the glandulae concatenatae, and sometimes in the axillary and inguinal glands. The glands slowly increase in size, at first remaining clearly defined and distinct from each other. They may after a time cease to enlarge, and remain permanently without further change; but more commonly, after continuing in this state for months or years, they soften. The inflammation then extends to the surrounding tissues, and the glands become adherent to neighboring parts and finally to the skin. Several glands may thus become fused together, forming a large

indurated and nodulated tumor. Suppuration takes place slowly, and the skin becomes thin, blue, and undermined. Finally, it gives way by a small opening, and curdy, unhealthy pus is discharged, mixed with the debris from the softened cheesy matter from the gland. The discharge may continue for weeks or months, being kept up partly by the gradual expulsion of the remains of the degenerated gland, and partly by the thinned and undermined skin being too feeble to take any part in healthy repair. The opening may close for a time, bursting open and discharging again at intervals. In other cases the thinned skin perishes, and the remains of the gland may be exposed as a reddish-gray or fleshy mass protruding in the midst of the sore. When these sores finally heal, they leave thin, blue cicatrices, finally forming irregular puckered scars.

TREATMENT.—The local treatment of inflamed lymphatic glands varies according to the variety of the process. In all forms the local irritation to which the inflammation is due must be removed if possible. In *acute lymphadenitis* the application of glycerine and extract of belladonna in equal parts, and hot fomentations may prevent suppuration. In the *subacute* condition, spirit lotions containing iodide of potassium will sometimes subdue the inflammation and take down the swelling. If an abscess form, it must be freely opened and the part dressed with some antiseptic application. The sinuses which are often left when the abscess is imperfectly opened, or allowed to discharge by itself, require to be treated by stimulating applications, especially the nitrates of silver; but very commonly they will not heal unless they are laid open and dressed from the bottom.

Chronic or Scrofulous Inflammation of the Lymphatic Glands requires to be treated on different principles. When there is merely chronic enlargement, without irritation, methodical friction with iodine or iodide of lead ointment will sometimes produce absorption of the inflammatory products, constituting the bulk of the enlargement; and this in some instances may remove the tumor entirely. In other cases, painting the part with tincture of iodine, and improvement of the general health, will cause the removal of the disease. When the gland has softened and is becoming adherent to the surrounding parts, it becomes an important question, at what period it should be opened, so as to insure the speediest recovery and the least scarring. It was formerly advised by many Surgeons to leave the gland until it became distinctly adherent to the skin, and until it was so completely softened that the whole of the cheesy matter might be discharged at the time of opening. The result of this plan was usually to leave a deep puckered scar, and healing was seldom complete for some weeks or even months. These unpleasant consequences can frequently be to a great extent averted by early opening, and free scraping with a sharp spoon (Fig. 95, vol. i.). As soon as the gland is evidently softening, the operation may be performed. The gland is steadied between the finger and thumb of the left hand, and a puncture made into it with a scalpel about a quarter of an inch in width. A probe may then be passed along the scalpel, so as to serve as a guide to the opening in the capsule. The scalpel is then withdrawn, and a small sharp spoon passed along the probe into the gland. By forcibly squeezing the gland and scraping with the spoon, the whole of its caseous contents can usually be removed without difficulty. A very fine drainage-tube may then be inserted for a few days, after which healing will probably take place without difficulty. The results of this little operation are very much better if strict antiseptic precautions are observed; for if the cavity becomes filled with decomposing discharges, troublesome diffuse suppuration may follow in the areolar tissue. Iodoform or salicylic wool forms the best dressing in most cases. If several glands lie close together, it is sometimes possible to scrape more than one

from a single opening. The scars left after this mode of treatment are very slight.

If an aperture already exists leading down to an indurated mass, the sinus may be freely scraped in the same way, and healing is often hastened by the insertion of a small quantity of iodoform into the track left after the operation. If after an abscess has formed and been opened, an irregular cavity is left with masses of degenerating gland-tissue projecting into it, these may be scraped away by a sharp spoon, or destroyed by *potassa fusa*. In applying the caustic potash, care must be taken that its action does not spread too widely; this may usually be avoided by coating the surrounding integuments with collodion. The blue undermined skin left after spontaneous bursting of a scrofulous abscess of the glands delays healing, and is useless itself for any purposes of repair. It must, therefore, be destroyed, however large the resulting sore may at first appear to be. This may be done by means of *potassa fusa*, but cutting it with scissors in a number of lines radiating from the central opening will usually make it in great part melt away, and, at the same time, is free from the risk of destroying more than is necessary.

Extirpation of chronically inflamed and caseating lymphatic glands has been recommended, with the view of preventing general tubercular infection; but, for this reason alone, it is not to be recommended. It is impossible, in the vast majority of cases, to remove all or nearly all the affected glands, and, if undertaken, it may lead to more serious and extensive dissections than might at first appear requisite; for a chain of diseased glands often extends a considerable distance, and after one has been removed others come into sight. Cases, however, occasionally occur, in which such a procedure may be deemed advisable, the affected glands being large and indurated, and the disease of many years' standing; their extirpation may then be proper, and I have not unfrequently had occasion in such circumstances to remove them from the axilla, from the submaxillary region, and from the posterior triangle of the neck.

The constitutional treatment of chronic strumous disease of the glands is fully described in the chapter on Scrofula and Tubercle, vol. i. p. 1022.

LYMPHADENOMA.

This disease has been already described in the chapter on Tumors, vol. i. p. 454, and but little remains to be said concerning it. When the disease is limited to the lymphatic glands, the question of their removal often comes before the surgeon.

If the tumor be large and single, or composed of an agglomeration of multiple masses, and so situated that it can be taken out with safety, its removal is proper, and should be practised. I have several times removed lymphadenomata from the axilla and upper part of the neck with great ease. Even when the disease is multiple, single large masses that are of special trouble should be dissected out. In one such case a tumor, as large as a fist, was removed, in University College Hospital, at axilla. The patient, a delicate woman, had a group of similar on the neck, which had remained stationary for twenty years. Operation should not be undertaken when the patient is very weak or, and more especially when there is persistent elevation of temperature. Accompanying figure (Fig. 423), from a patient under the care of Mr. Heath, is a good illustration of the appearances produced by when affecting the glands at the root of the neck.

With the exception of lymphadenoma, the lymphatic glands are singularly exempt from the growth of primary tumors. Round-cell sarcoma is said occasionally to be met with, but it is probable that some of the tumors formerly described under that name would now be classed as lymphadenoma.

Fig. 423.—Lymphadenoma of Glands at Root of the Neck.

mata. Secondary tumors are, however, extremely common. All forms of cancer tend to affect the glands at an early period of their growth. Round-celled and melanotic sarcomata also frequently give rise to secondary tumors in the glands.

CHAPTER XL.

DISEASES OF VEINS.

VENOUS THROMBOSIS.

Thrombosis, or coagulation of the blood in the vessels during life, is very common in the veins.

Causes.—The views generally entertained at the present time with regard to coagulation are that fibrin does not exist as such in the blood, but is formed by the union of two substances, fibrinogen and paraglobulin, under the influence of a third body of the nature of a ferment, known as the fibrin-ferment. The fibrinogen is always normally present in the blood-plasma and the paraglobulin is supposed to be contained chiefly in the white corpuscles. The fibrin-ferment is not supposed to be present in a free state in the blood.

as it circulates in the body, but is liberated from the white corpuscles under certain conditions. Blood in contact with the walls of vessels, which, to use Cohnheim's expression, are in a state of "physiological integrity," shows no tendency to coagulate, but when it is brought in contact with dead matter clotting takes place. In the same way, if the integrity of the vessels is damaged by disease or injury fibrin becomes deposited at the damaged spot. The presence of free ferment in the blood may also cause coagulation in the living body. Kabler has shown that if a sufficient quantity of fibrin ferment be experimentally introduced into the blood-stream, rapid coagulation will take place, even in contact with healthy vessels. If a smaller quantity is injected there is severe febrile disturbance, but thrombosis does not take place, the influence of the healthy walls of the vessels being then supposed to be sufficient to arrest coagulation until the ferment is eliminated from the blood. Retardation, or arrest of the blood-stream, acts as a powerful predisposing cause of thrombosis. These conditions apply equally to all vessels, whether arteries, capillaries, or veins, but we have to consider them here in reference to the veins only.

The causes of venous thrombosis may thus be classified :

1. Changes in the condition of the wall of the vessel due to (a) injury, (b) inflammation; (c) degeneration.

2. Altered conditions of the blood in which there is supposed to be a liberation of the ferment.

3. Retardation or arrest of the blood-stream; due to (a) diminished *vis a tergo*; (b) pressure on the vessel; (c) interruption of its continuity; (d) obstruction by a thrombus due to any of the preceding causes.

1. *Changes in the wall of the vessel.*

a. Injury.—The effect of any severe injury to the coats of a vein is either to extinguish, or so far to diminish, the vitality of the injured part, that it behaves toward the blood as a foreign body and a coagulum is formed on the damaged part just as it would be on a piece of wire introduced into the vein. Veins are occasionally penetrated by foreign bodies, as when a ligature is accidentally passed through a vein in ligaturing a contiguous artery. Under these circumstances a clot will quickly form upon the foreign body.

b. Inflammation.—It has already been pointed out in the chapter on Inflammation that the most essential feature of the process is a diminished vitality of the affected part to a degree short of actual death. If the inflammation is sufficiently intense the wall of an inflamed vein behaves towards the contained blood as if it were dead matter, and coagulation consequently takes place. Thrombosis thus forms a marked feature of all forms of phlebitis. The causes of inflammation of veins will be described later on (see Phlebitis).

c. Degeneration.—Degeneration of the coats is less marked in the veins than in the arteries. In varicose veins, the middle coat is greatly thickened by the growth of fibroid tissue, and calcareous plates are sometimes met with in it; but the endothelial lining is usually intact, and consequently thrombosis comparatively rarely takes place as a consequence of this alone.

2. *Altered conditions of the blood.*—The exact nature of the changes of the blood that predispose to thrombosis is very imperfectly known. The experiments before alluded to show that an excess of free ferment in the blood may act as a powerful predisposing cause, or even the sole cause of coagulation. In septicæmia, pyæmia, and many other acute febrile diseases, there is considerable destruction of the corpuscles, and very probably in this way ferment is liberated, and it is well known that thrombosis is common in these affections. The mere excess of white corpuscles, such as is observed in leu-

coccythæmia, does not seem to predispose in any great degree to thrombosis. Koch has observed, in pysemia experimentally induced in animals, thrombosis of small vessels apparently originating in the plugging of the channel by microscopic organisms, and possibly some such condition may be concerned in some cases of venous thrombosis.

3. *Retardation of the blood-stream.*—Perfect rest of the blood when withdrawn from the body delays coagulation, and free movement hastens it. It is impossible, therefore, to suppose that retardation or arrest of the flow can act directly as a cause of thrombosis. Nothing, however, is more certain than that it does form one of the most important causes of coagulation in the living vessels. It may act in various ways. First, if the arrest of the circulation be complete and of sufficient duration, the vitality of the part will suffer until the vessels come to act as foreign bodies and coagulation takes place. Secondly, if a part of the vein is already diseased or injured the retardation of the blood-stream will favor the adhesion of the white corpuscles to the unhealthy surface, which is the first step in thrombosis when the blood is still moving. Thirdly, if the blood stagnate for a sufficient time the white corpuscles may perish from want of oxygen and disintegrate, thus liberating the ferment and inducing coagulation. Lastly, it is possible that the nutrition of the endothelium may suffer from arrest of the flow of blood through the vessel even when the circulation through the surrounding tissues is sufficiently active to maintain their vitality.

Retardation or arrest of the blood-stream may arise (a) from diminished *vis a tergo*. This may be due to want of power in the heart from old age, bad nourishment, exhausting fevers, or from shock, loss of blood from injury or operation. Interruption to the proper distribution of the force through want of elasticity in the arteries acts in the same way. Obstruction of the main artery of a limb or arrest of the capillary circulation from which a vein derives its blood, will in like manner retard the venous flow. Another very common cause of retardation or arrest of the blood-stream in the veins is the obstruction caused by the presence of a tumor, or the contraction following chronic inflammation of the connective tissue of an organ; examples of these conditions may be frequently seen in the iliac veins pressed upon by a pregnant uterus, or an ovarian tumor, and in the vessels of a cirrhotic liver: and it must be remembered that a tight bandage may act in the same way.

When a vein is divided in a surgical operation, it empties itself and becomes collapsed as far as the next pair of valves, but above these it may remain full of stagnant blood up to the point at which another vein enters the trunk. When a vein is ligatured in its continuity there will be, in addition, stagnation of blood below as far as the next collateral branch.

When the circulation is too feeble to press the valves back against the walls of the vessel, or when in consequence of dilatation they are never properly closed, but project into the lumen of the vein, it not uncommonly happens that stagnation takes place in the sinuses of the valves, and small thrombi may thus form, which finally project into the lumen of the vessel, and by gradual increase may at last close it completely.

The Process of Thrombosis.—Thrombosis may take place while the blood is moving, the lumen of the vein becoming gradually filled with the coagulum, or while the blood is at rest.

The appearance of the thrombus varies with the conditions under which it is formed, much as the coagulum obtained by whipping blood differs from that formed when freshly shed blood is allowed to coagulate undisturbed in a vessel. The process of thrombosis has been observed experimentally by Zahn in the veins of the mesentery and tongue of the frog. A large vein

being chosen, its walls were injured by placing a crystal of common salt near or directly over it. On watching the injured spot, the white corpuscles of the passing blood were seen to adhere to it until they were heaped up, sometimes to such an extent as to obstruct completely the vein. If the caustic action of the salt had not been very severe, they might break loose again and pass away into the blood-stream; if it had been more powerful, the corpuscles remained adherent. After some hours they were seen to undergo a marked change. The greater part disintegrated, their outline being lost and their nuclei no longer being recognizable, and a fine granular mass, having the appearance of freshly formed fibrin, appeared in the place they formerly occupied. This observation is in harmony with the view that the liberation of the ferment by disintegration of the white corpuscles plays an important part in the process of coagulation. The thrombus thus formed was in some cases pure white in color, but more commonly a few red corpuscles were entangled amongst the white. The more rapidly the plugging of the vessel took place the more red corpuscles were entangled in the thrombus. When coagulation takes place in a vessel in which the flow is completely arrested the clot differs in no respect from that formed in blood drawn from the body. It entangles in its meshes all the corpuscles, both red and white, and presents the familiar dark red color.

These observations explain the different appearances of the thrombus under the different circumstances in which thrombosis takes place. The clot formed above an injury which completely obstructs a vein, as when it is divided or tied, is uniform in structure, dark red in color, and at first but loosely adherent to the inner coat of the vessel. At a later period, as in the case of a ligatured artery, it becomes denser in consistence from contraction, and more firmly adherent, and loses its color in consequence of disintegration of the red corpuscles. A thrombus formed by gradual deposit from the circulating blood upon the unhealthy walls of a vein is either white or mixed in tint, according to the rapidity with which it is formed. It is firmly adherent to the inner coat of the vein and laminated in structure. Microscopic examination shows it to contain a few red disks, but numerous white corpuscles which have escaped disintegration are usually found between the laminae.

As a rule, the thrombi arising in cases in which an altered condition of the blood is supposed to be the cause of coagulation are white or mixed, the fibrin being deposited gradually on the walls of the vein, starting from some point where from disease or injury the endothelium is damaged.

When a vein is completely obliterated by a white thrombus, the stagnant blood on each side coagulates, forming a red clot adherent to the white. After death a further extension of this red clot takes place. These post-mortem clots are recognized by their softness and by their floating free in the vessel.

Cornil and Ranvier have supposed that in many cases at least the central portion of a laminated clot, and not its peripheral layers, are the oldest, the fibrin having been first deposited on the wall of the vein and then separated from it by contraction, though prevented from passing on towards the heart by the prolongations extending into the collateral branches. This view, however, seems far from probable. The only appearance suggesting such a process is met with in the clots extending from the heart into the pulmonary artery in cases of cardiac thrombosis. These are commonly found to fill the vessel incompletely, and often present perfect casts of the pulmonary valves. In these places, however, the coagulation takes place immediately before death, and very probably the contraction is post-mortem.

The **Fate of the Thrombus** varies according to the circumstances in which it is placed and the causes of its formation. Thrombi arising from injury

undergo the same changes as those forming in arteries under similar circumstances (vol. i. p. 308). The restoration of the channel through a vein, when the continuity of its walls has not been interrupted, takes place more readily than in similar conditions in the arteries. It is possible that in some cases this may result from disintegration of the clot, the débris being carried away and lodged in the lungs, where, if non-infective in character, they would cause no serious symptoms. The normal process of restoration, however, is effected by the clot becoming infiltrated by new cells proceeding from the wall of the vessel, as in the permanent closure of a divided vein. New vessels afterwards penetrate amongst these cells, and by means of these a communication is established between the permeable portions of the vein above and below the clot. The channel, at first small, gradually enlarges by absorption of new tissue through which it passes, and thus, at last, the full calibre of the vein is restored.

Softening and Disintegration are common changes when the thrombus has been formed in consequence of inflammation of the vein, or as a result of those altered conditions of the blood which accompany septicæmia or malignant fevers. It is a very frequent occurrence when the affected vein leads from a wound, the discharges of which are in a septic state, or from an area affected with some infective inflammation, as in acute necrosis of bone.

Softening most commonly takes place in white or mixed thrombi. It commences in the centre of the clot at the part furthest removed from the walls of the vein. The clot if mixed becomes completely decolorized, and gradually breaks down into a creamy fluid resembling pus in appearance. Microscopic examination, however, shows that it is not pure pus. In some cases it is composed merely of granular débris, no corpuscles of any kind being recognizable; in others a certain number of pus cells may be mixed with the débris. These are white corpuscles, which were either contained in the clot and have escaped disintegration, or have wandered into it from the surrounding parts. In most cases in which softening takes place, micrococci are found in abundance in the puriform fluid. The effects of the process of softening will be discussed immediately.

Calcification of a Thrombus is of rare occurrence. It occurs chiefly in the small clots that form in varicose veins in the pouches behind the valves. These calcified clots form small rounded bodies, varying in size from a mustard seed to a pea, and are known by the name of phleboliths.

Effects of Thrombosis.—The first effect of thrombosis when not arising from obstruction is necessarily to arrest the flow of blood through the vein. If a single superficial vein is obstructed, this may cause no marked symptoms; but when the clot is situated in a main trunk, as in the femoral at the groin, great œdema of the parts below results. This is commonly seen in the so-called "white-leg," which occurs after labor. If the vein remains permanently obstructed, the œdema may subside after some weeks or months, the collateral veins gradually dilating, and the free return of the blood being thus re-established. In other cases the œdema diminishes, but does not completely disappear, the limb swelling considerably when in a dependent position. When this occurs, the areolar tissue is indurated, the œdema becoming more "solid" as time goes on. The nutrition of the parts is interfered with, and chronic eczema or ulceration of the skin from slight causes is not uncommon.

The relation of thrombosis to inflammation of the vein is a subject on which there has been considerable difference of opinion. Pathologists in the early part of the century regarded the presence of a thrombus in a vein, except when obviously due to mechanical causes arresting the flow of blood, as evidence of previous inflammation of the coats of the vessel. Some later

pathologists, on the other hand, have maintained that when thrombosis is found associated with inflammation of the coats of a vein, the latter condition is always secondary to the former. The truth probably lies between the two views. A vein may become inflamed as the result of mechanical violence, or of being laid bare in an operation, and subsequently exposed to the contact of decomposing discharges, or by being implicated in unhealthy ulceration of the surrounding structures. In other cases diffuse inflammation may spread from a septic wound in the loose areolar tissue surrounding the vein. In all these conditions the phlebitis precedes the thrombosis. The opposite condition may be met with when a vein has been wounded, and its divided end filled with a clot is exposed in a septic wound. The clot then becomes impregnated with septic matter, and fresh coagulation takes place upon its proximal extremity; septic disintegration of the clot follows, and the coats of the vein become inflamed from the contact of the irritating products of the process. Thus a spreading thrombosis, followed by disintegration of the clot and inflammation of the vein, may be set up. This is a condition frequently met with in pyæmia, and is especially common in the infective inflammation of bone known as acute necrosis. In some cases of pyæmia, thrombosis, with softening of the thrombus and inflammation of the coats of the vein, is met with in parts having no connection with the original wound. Here also it is only reasonable to suppose that the irritating properties of the thrombus are due to the presence of the infective material in the blood from which it is formed. Simple coagulation of healthy blood in a vein does not cause acute inflammation of the coats of the vessel. After the operation for varix the vein can often be clearly felt on each side of the obliterated spot as a solid cord, but none of the signs of phlebitis are present.

The most serious consequence of venous thrombosis is *Embolism*, or the separation of a clot, and its entry into the circulation. When the formation of the thrombus has been due to mechanical injury, this complication rarely takes place. Occasionally, however, after a surgical operation or parturition, a large clot may be dislodged and cause sudden death by obstructing the pulmonary artery. If the clot is not large enough to obstruct the main trunk of the artery, it may lodge in a smaller branch. A typical case of this kind occurred not long ago in University College Hospital. The patient had been confined to bed for some weeks with a compound dislocation of the ankle; the wound was nearly healed, and he was apparently in good health. He suddenly woke from sleep with a violent pain, which seemed to shoot up from his leg to his chest. There was immediately intense sense of dyspnoea, although the air entered the lungs freely; the pulse rose to 120, and the action of the heart was violent and irregular. The symptoms gradually subsided, and on the third day after the attack he expectorated a small quantity of blood. Within a few hours of the attack, the symptoms of obstruction of the femoral vein manifested themselves. It was slightly tender, and could be felt as a hard cord, and great oedema of the limb appeared. Some weeks after, the veins of the opposite limb became plugged in the same way, but no embolism took place.

Embolism is more commonly the result of softening and disintegration of the clot. It is possible that a healthy clot may in this way be removed without giving rise to any definite symptoms. When the softening is due to septic changes in the thrombus, or when the clot is impregnated with the products of an infective inflammation of any kind, the virulent fragments set up inflammation wherever they lodge, giving rise to the form of general infection known as embolic pyæmia. The pathological effects of simple and infective embolism have been already described (see *Pyæmia*, vol. i.).

A softening thrombus does not necessarily give rise to embolism. In the common form of so-called idiopathic phlebitis, suppuration frequently takes place round the thrombosed vein, the middle part of the thrombus is softened, the walls of the vein give way, and the debris of the clot are discharged with the pus of the abscess. In these cases a portion of the thrombus on each side remains unsoftened, and undergoes the ordinary changes observed in closure of a divided vessel.

The SYMPTOMS of thrombosis are merely those of obstruction of the vein. If superficial, the vein can be felt as a hard cord, with knot-like projections at the situations of the valves. If a deep vein is affected, there is œdema of the part from which it comes, often with dilatation of the superficial veins. The swollen parts are white, and pit deeply on pressure. When the coats of the vein are inflamed, the symptoms of phlebitis to be presently described will be manifest.

The TREATMENT depends entirely on the cause. When it is a part of the pyæmic process, it is that of pyæmia; when associated with phlebitis, it must be treated as described under that disease. Œdema must be treated by elevation of the limb and careful bandaging with an elastic or stocking bandage. In all cases perfect rest of the part must be maintained, in order to obviate as far as possible the risk of embolism.

PHLEBITIS.

Inflammation of the Veins, originally studied by Hunter, has in later years attracted the attention of many distinguished Continental and British pathologists, amongst whom may be specially mentioned Breschet, Velpeau, Cruveilhier, Arnott, Henry Lee, Tessier, and Virchow.

CAUSES.—Phlebitis may arise from injury of the coats of the vein, from inflammation of the tissue surrounding it, periphlebitis, or from the formation of an unhealthy thrombus within it. Each of these causes may occur separately, but frequently more than one are concerned in the process. In other cases phlebitis is said to be idiopathic, which means that the cause cannot be accurately ascertained.

Traumatic phlebitis may be simple and localized, or septic and spreading. The coats of a vein, in the same way as any other tissue, become inflamed if submitted to any injury of sufficient intensity, whether it be the application of a ligature in a surgical operation, accidental mechanical violence, or the action of caustics. As the result of the injury, a clot forms within the vein, adherent to the damaged spot. If this completely occludes the vessel, it extends upwards and downwards as far as the vein contains stagnant blood. The inflammation is, however, limited to the injured spot, and shows no tendency to extend. Ultimately the clot may become absorbed, and the channel of the vein restored, or the vessel may become permanently obliterated by the processes already described as occurring in arteries under similar circumstances.

Traumatic phlebitis does not, however, always run this simple course. When the discharges of the wound through which the vein has been injured are in a septic condition, and the plugged vein is exposed to the direct contact of putrid matter, the thrombus may become infected. It then softens and decomposes, and thus excites inflammation in the coats of the vein, spreading beyond the part originally injured. Fresh clot, which in its turn decomposes, forms in the vein as far as the inflammation extends; and so the process may spread until some part is reached at which a large vein joins the affected trunk, when fragments of the softening clot are washed on, giving rise to the dissemination of septic emboli and pyæmia. It is this

form of spreading phlebitis that was formerly so common in hospital practice. The earlier pathologists regarded the spreading inflammation of the vein as the primary cause of the mischief, whereas it is evident that it is really due to the changes taking place in the thrombus.

Spreading phlebitis may arise also without an injury in the veins leading from many infective inflammations. Either the trunk may be involved in the inflamed area or thrombosis may extend into it from the smaller veins and venules. In either case the clot becomes impregnated with the infective material, and undergoes changes of the same character as those just described.

In some cases of pyæmia or septicæmia, thrombosis may occur, as has been already pointed out, in parts distant from the seat of infection, and in these cases it softens and causes inflammation of the coats of the vessel. It is a possible explanation of this phenomenon that the blood contains before coagulation some noxious material, which causes the subsequent softening and disintegration. In support of this theory is the fact that micrococci are found abundantly in the debris of the broken-down clot.

Diffuse inflammation spreading from an unhealthy wound along the areolar tissue surrounding a vein may, in some cases, give rise to inflammation of its coats.

In addition to the above forms of the disease, phlebitis is frequently met with without our being able definitely to explain its mode of origin, and it has therefore been said to be idiopathic. This form almost invariably affects one of the large veins of the lower extremity, usually the saphena, but occasionally the popliteal, femoral, or iliac. Most commonly the vein attacked has long suffered from varix. It seems to be most frequent when erysipelas is epidemic, but the relation between the two affections is not proved. The inflammation extends to the surrounding areolar tissue, and may occasionally, but rarely, end in suppuration. The clot then disintegrates, the walls of the vein give way, and the debris mix with the surrounding pus; but even when this happens, there is but little tendency to extension of the mischief, the disintegrating clot being shut off on each side by an adherent unsoftened thrombus. When suppuration does not follow the risk of disintegration and embolism is very slight, but it does sometimes occur and cause death.

Sir James Paget has pointed out that "idiopathic" phlebitis commonly affecting the long saphenous, but occasionally the deeper veins, is not uncommon in gouty subjects. It may occur in different parts of the same vein at the same time, and is very liable to relapse. He has termed the affection "gouty phlebitis," and believes that it commences as a gouty inflammation of the coats of the vein.

PATHOLOGICAL ANATOMY.—The coats of an inflamed vein are swollen and rigid, and of a redder tint than natural from injection of the vessels of the outer coat. The surrounding tissues are usually oedematous. In septic or infective phlebitis the walls of the vein are softened, and often give way opposite the disintegrating portions of the clot, and wherever this happens a collection of pus forms outside the vessel. The conditions of the thrombi in inflamed veins have already been sufficiently described (see Venous Thrombosis). Microscopic examination shows the coats of the vein to be infiltrated with small round cells, the endothelium is at first swollen, and if softening of the thrombus takes place is lost in the disintegrating clot.

SYMPTOMS.—In idiopathic or gouty phlebitis of a superficial vein the symptoms are very evident. The patient has usually suffered from varicose veins before the attack. The inflammation is localized, usually affecting a few inches of the vessel, and sometimes two or more parts at the same time. The vein becomes hard, swollen, knobbed, and painful, the knobs constituting

distinct enlargements opposite the valves, or in the pouch-like dilatations of the varicose vein. The skin covering it assumes a reddish-purple color, and there may be stiffness, or inability to move the limb. There may, perhaps, be no pain when the limb is at rest, but in some cases there are severe shocks of pain, resembling neuralgia, darting through the limb. In all cases there is acute tenderness over the course of the vessel. There is always some œdema around the inflamed vein, but if a single superficial vein is affected there is but little swelling of the parts that supply it with blood, owing to its free communications with the deep veins.

When the deep veins are affected the most marked signs are deep-seated acute pain and tenderness, with marked œdema of the parts from which the vein derives its blood. This œdematous condition of the limb is a most important diagnostic sign of deep-seated phlebitis when the vein cannot be felt (as in the pelvis, for instance), and may be the first symptom observed, coming on either suddenly or gradually. The œdema may give rise to a hard, white, tense condition of the limb, which pits on pressure, though in some cases the hardness is too great for this, such as is seen in the ordinary "white leg" of the *accoucheurs*. Occasionally in deep phlebitis the limb may suddenly swell to a considerable size without there being any subcutaneous œdema. In phlebitis of the deep veins of the leg and thigh, the calf of the affected limb may suddenly enlarge, with great pain and much distention of the superficial veins with fluid blood, but without any subcutaneous œdema. As the inflammation subsides the pain and tenderness disappear; and if superficial, the distended vein, with its solid contents, becomes more clearly defined. In varicose veins complete obliteration of the vessel may take place, the hard cord gradually diminishing in size till it is no longer perceptible. If the deep-seated veins are affected, the œdema continues long after the signs of inflammation have disappeared, perhaps for many months, till either the channel of the vein has been restored, or the superficial veins have enlarged sufficiently to carry back the blood without difficulty. If suppuration takes place in phlebitis of a superficial vein, the symptoms are those of an ordinary acute abscess. When the deep veins are affected, the symptoms are less clear until the accumulation becomes of sufficient size to give a distinct sense of fluctuation. In these cases there is but little fear of pyæmia, as the vein is closed by a firm adherent clot on each side of the part in which suppuration is taking place. After the resulting abscess has been opened, however, spreading septic phlebitis, followed by pyæmia, is very apt to occur unless proper antiseptic precautions are taken to prevent it. The constitutional disturbance in this form of phlebitis is not severe unless suppuration takes place, and even then it speedily subsides as soon as the pus is evacuated.

The symptoms of *spreading septic phlebitis* of the deep veins are less evident, being concealed more or less completely at first by the unhealthy inflammation taking place in the part from which the mischief has started, and later on by the grave constitutional symptoms of pyæmia which speedily manifest themselves. Pain and tenderness in the line of the vein, with considerable œdema rapidly coming on, would lead to a suspicion of its occurrence. The superficial veins are less commonly affected, but should it happen, the symptoms are those just described of superficial phlebitis, differing only in the steady extension of the redness and pain up the course of the vein, and in the presence of the general symptoms of blood-poisoning.

TREATMENT.—The first point to be attended to in the treatment of phlebitis is absolute rest of the limb in an elevated position. The importance of rest in these cases is twofold; first, to prevent pain and increase of the local mischief; and, secondly, to guard against the danger that may result from the detachment of the thrombus, which, carried into the circulation,

may occasion sudden death by plugging of the pulmonary artery, or more remotely, in cases of septic phlebitis, by pyæmia.

In simple or gouty phlebitis, much local comfort is derived from the application of extract of belladonna and glycerine, in equal parts, covered by a thick layer of cotton-wool and a bandage. Should this application not be at hand, hot fomentations will afford great relief. The constitutional treatment must be conducted on ordinary medical principles in accordance with the age and strength of the patient, always avoiding depletory measures, which are not well borne, and early having recourse to a tonic or stimulating plan. The hardness that is often left after subsidence of the inflammation may be removed by salt and nitre poultices, as recommended by Basham. If œdema of the limb continue, the pressure of an elastic roller will remove it. But if the œdema has been extensive and chronic the limb rarely, if ever, completely recovers its natural size.

If abscesses form they must be treated by free and early incisions, and the most scrupulous attention being paid to the prevention of decomposition.

In spreading septic phlebitis treatment is of little avail. If a superficial vein is affected, it would be justifiable to expose the vein above the affected part and remove a portion of it to arrest the progress of the disease. If the deep veins are affected and the diagnosis can be clearly established, and especially if rigors and other symptoms of blood-poisoning are present, amputation may give the patient a last chance. This form of phlebitis is, however, almost certainly preventable by any efficient antiseptic mode of treating wounds.

In those cases in which a similar condition is set up in the vein leading from an area of infective inflammation, not septic in character, as in acute necrosis of the bone the diagnosis is almost impossible till it is too late for amputation to be of any service.

VARICOSE VEINS, OR VARIX.

By **Varicose Veins**, or **Varix**, is meant a permanent dilatation of the veins with thickening of their walls. It must be distinguished from simple dilatation or phlebectasis such as arises from acute obstruction to the return of blood, or from the pressure of a tumor or aneurism. Simple dilatation subsides as soon as the cause is removed, and it is not accompanied by any definite change in the structure of the walls of the vein; varix is permanent, and is always associated with degenerative changes in the coats of the affected vessel.

CAUSES.—The causes of varix are generally *such conditions as induce more or less permanent or frequently repeated distention of the veins*. Thus, for instance, strains and habitual overexertion of the limb, by driving the blood from the deep into the subcutaneous veins, may give rise to their distention; so also sedentary occupations and prolonged standing tend to favor accumulation of blood in the veins of the lower extremities. Any obstacle to the return of blood from a vein (as the pressure of a tight garter below the knee, or of a tumor upon one of the large venous trunks), may give rise to permanent distention if it act for a sufficient length of time. When the vein has become sufficiently dilated to render its valves incompetent, the tension of the walls of the veins is greatly increased by the weight of the unbroken column of blood, and the condition thus becomes aggravated. In all cases in which the tissues are congested from any obstruction to the return of blood to the heart, the walls of the veins suffer with the other parts, and thus are rendered more prone to undergo degenerative changes.

In some cases the affection, or the disposition to it, appears to be *heredi-*

tary; and in many instances it is difficult to recognize any cause except an *enfeebled and relaxed state of the walls* of the vessel, such as is met with in tall, debilitated, and phlegmatic people. Age influences materially the occurrence of the disease, which, rare in the earlier periods of life, gradually increases in frequency as the individual advances in years up to the middle period of life when the tendency ceases. In *women*, especially, the affection is common; in consequence, partly, of natural debility, but more frequently from the pressure of the enlarged uterus during pregnancy.

LOCALITY.—The veins of the skin and the mucous membranes are those that are most liable to varix. It is most commonly met with in the legs, and more particularly in the trunk of the internal saphena. Simple dilatation may be met with in any of the superficial veins, as of the chest, arms, head, neck, hypogastrium, or thorax, but true varix in these situations is rare. The veins of the anus and lower part of the rectum are especially liable to varix, as they are but loosely supported by the surrounding parts, and are liable to over-distention from any cause that obstructs the hepatic circulation, such as a cirrhosis of the liver. The spermatic veins also often become enlarged, constituting varicocele.

True varix is infinitely more common in the lower than in the upper part of the body, owing evidently to the influence of gravity in causing tension in the more dependent vessels. Dilatation of the veins at any point above the pelvis arises in most cases from the pressure of a tumor of some kind upon the large venous trunks, the superficial veins being enlarged to take the place of the deeper vessels that are obstructed. This condition may end in true varix, but if the enlargement is sufficient to enable the vein to carry the required quantity of blood easily there will be none of those changes of the coats which constitute true varix and are the result of abnormal tension. The deep-seated veins that are principally affected are the internal jugulars, the vena azygos, and the veins of the prostate.

MORBID ANATOMY.—Veins that are simply dilated differ from true varicose veins in being merely increased in size, without any alteration in structure. Their walls are thin and soft, and they collapse readily. A varicose vein is increased in diameter and elongated, forming curves and bending back on itself. Sometimes the enlargements at particular points appear multilobular, the vein forming a series of curves and lying closely packed together. The coats of the vein are opaque, and thickened often to such an extent that the divided vessel stands open like an artery. Occasionally calcareous plates are met with in the thickened walls. On opening the vein the valves are always found to be insufficient; sometimes they have disappeared altogether, and in other cases they form small ridges or bands projecting from the wall. When the vein has been cut up, it will be seen that in some of the pouch-like dilatations the wall has become greatly thinned. The inner coat of the vein appears smooth and but little altered, beyond being often marked by longitudinal striæ. When the vein is subcutaneous, the small branches entering the trunk from the skin are often dilated, and this condition may sometimes be traced here and there into the cutis, which is thinned over the dilated vessel. In the wall of the vein and in its sheath small dilated veins belonging to the vasa vasorum are very commonly observed.

Microscopic examination shows that the thickening of the vein is chiefly due to a development of dense fibroid tissue in the middle coat. The muscular fibre-cells are somewhat increased in number, but are separated widely from each other by the fibroid tissue. The outer coat is also thickened; the inner shows but little change. In the thinned pouches, the middle coat is atrophied, and may have completely disappeared.

APPEARANCES AND SYMPTOMS.—Varicose veins are tortuous, dilated, and sacculated; they are serpentine in their course, and feel thick under the finger. When superficial, the disease is often limited to one of the larger venous trunks, the smaller branches not being engaged. This we commonly see in the internal saphena. The pouch-like dilatations may often approach very closely to the surface, the skin being thinned over them, and the blue tint of the skin being readily perceptible. When the patient is erect, the vein becomes more prominent and tense. In other cases the small superficial veins are affected, appearing in the skin as a close network of a purplish-blue color, causing much discoloration of the parts. Both sets of vessels may be implicated. In consequence of the incompetence of the valves, an impulse can often be felt even below the knee when the patient is made to cough. Varix of the deep veins is less common, as the vessels are better supported by the surrounding parts. They give rise to no appearance which can be recognized during life. Varicose veins cause a sense of tension and weight, often with considerable smarting or pricking pain in the parts from which they return the blood. Sometimes they may cause numbness, difficulty of movement, or even some loss of power in the affected limb. These symptoms are aggravated by exertion. In deep-seated varix, these symptoms are often very marked.

PROGRESS AND EFFECTS.—Varicose veins never undergo spontaneous cure; when once formed, the condition is permanent, unless the vessel become plugged by coagulum, when it may be obliterated. The current of blood is then diverted into other channels, and, as a rule, these in their turn become varicose. The main evil that results from varicose veins in the legs, is the change that is slowly induced in the nutrition of the skin, and subcutaneous areolar tissue, by the retardation of the circulation, and the interference with the due return of blood. The parts from which the vein derives its blood are often slightly cedematous. After a time the subcutaneous fat becomes indurated, and the skin loses its elasticity, becomes rigid, and often darkly pigmented in places. In consequence of the imperfect nutrition of the parts ulceration frequently takes place, especially below the middle of the leg. The ulcer has a great tendency to assume the chronic or callous form. Chronic eczema is a frequent consequence of the congestion of the skin caused by varicose veins. There is another accident that may occur as the result of varicose veins of the legs, viz., that the varix may give way, the vein may "burst" as is generally said. In these cases, the word "burst" is scarcely correct. The varix does not give way solely by pressure from within, but a process of ulceration goes on from without by which its coats become weakened, so that at last a pinhole aperture forms, giving rise to profuse hemorrhage. The bleeding is often so profuse as to induce faintness, and sometimes even death in a few minutes. This bleeding takes place in a different way from ordinary venous hemorrhage, the blood coming chiefly from the cardiac and not the distal side, the incompetent valves not presenting the ordinary obstacle to the downward flow of blood. It is this that causes its extraordinary copiousness. In most cases this so-called "bursting" is not so sudden but that a Surgeon may foresee the probability of its occurrence, as it most commonly takes place either on the surface of an ulcer, or is preceded by induration, reddening, and thinning of the integuments covering the diseased vein. In some cases, however, the warnings may be very slight. A few years ago a man was brought into University College Hospital who had died in a few minutes from hemorrhage from a varicose vein. There was nothing to be seen on the body but a minute hole, surrounded by apparently healthy skin. Water injected into the vena cava readily flowed out through the aperture. On injecting the specimen

and dissecting it, a large mass of tortuous veins was found, but the hemorrhage had come from a small cutaneous vein which joined the dilated trunk. It had been dilated to the size of a crow-quill, and the cutis covering it was thinned. Varicose veins are very prone to suffer from inflammation and thrombosis. The symptoms are those of phlebitis, already described. The inflammation is always localized. Suppuration occasionally takes place, but spreading phlebitis and embolism are rare complications. After an attack of phlebitis the vein is often obliterated, and the patient cured of his disease.

TREATMENT.—This must be conducted on two principles—to palliate and to cure. The **Palliative Treatment** consists in moderate compression exercised upon the vessel, so as to support its weakened and dilated coats, and thus prevent its further distention and the pain occasioned by this, as well as the other consequences—such as œdema, induration, and ulceration. The pressure must be applied very smoothly and evenly, lest it irritate the skin, and cause ulceration, or produce distention of the vein below the part compressed. For the purpose of compression, bandages and elastic stockings are commonly employed. The soft “stocking bandage” is one of the most comfortable. If an elastic stocking be used, care must be taken that it really fits evenly. They are often made too tight at the upper part. Martin’s India-rubber bandage, applied in the same way as in the treatment of the chronic ulcer (vol. i. p. 278), is a most efficient and comfortable mode of treatment if the patient can wear it without its causing eczema. Elastic pressure by means of a vulcanized India-rubber band or garter applied around the limb, so as to simulate the action of the valves of the vein, and by its compression to cut off the weight of the column of blood from the terminal branches, has been recommended; and Colles advised the application of a truss to the upper part of the saphena vein; but, as a rule, these modes of treatment only aggravate the symptoms.

If a vein burst, the hemorrhage is easily arrested by placing the patient on his back with the leg elevated and applying a compress and bandage. When a patient is in danger of hemorrhage, he should be advised to have the vein at once obliterated; and if this cannot be done, he should be warned and told that if bleeding comes on he has nothing to fear, if he lies on his back and elevates his leg against some convenient object nearly to a right angle with his body, till assistance can be obtained. The application of a finger to the bleeding spot would immediately arrest the hemorrhage. When death takes place, it is while the patient is foolishly running about to seek assistance, the bleeding coming from above, not from below the opening.

In certain circumstances, it becomes necessary to change the palliative for a **Curative plan**. This is especially requisite in the following three conditions: 1, if the varix be so large as to produce much inconvenience, or to give rise to severe pain by its pressure on the nerves in its neighborhood; 2, if a varicose vein have burst, or be on the point of giving way; or, 3, if an ulcer dependent on its existence will not heal. Various plans of curative treatment have been recommended; most of which have for their object the obliteration of the vein at one point by exciting inflammation there, and thus causing it to be filled by a thrombus which will extend as far as the next branch on each side. Finally, the vein becomes obliterated and reduced to a fibrous cord. As the treatment involves the artificial excitation of phlebitis and thrombosis, there is necessarily some little risk of its assuming a spreading form with softening of the clot and subsequent pyæmia. This, however, could occur only if septic inflammation were set up round the vein as a consequence of the wound made in the operation, or if the patient at the time of the operation was suffering from some serious general dis-

case. By a little caution, therefore, such accidents can almost certainly be prevented.

By these means the trunk of a varicose vein and the larger masses of varix may be occluded. But can the disease be cured by the local obliteration of the vein? To this question, I have no hesitation in answering in the negative. Though the trunk be obliterated, a collateral venous circulation is set up, which is very apt in the course of a few months to take on a varicose condition, and thus to cause a return of the disease. But, though the cure be not radical, much benefit may often be effected by removing varicose knots that occasion pain or inconvenience, by enabling an ulcer to cicatrize, or by occluding a vein from which hemorrhage has occurred or is threatening to occur. Various plans for obliterating the veins have been recommended. They resolve themselves into five principal heads of treatment.

1. *Division of the Vein* has been done by a subcutaneous incision followed by the application of a compress and bandage. Excision of a portion of the vein between two ligatures is a most efficient mode of treatment, and can be safely undertaken if any efficient mode of antiseptic treatment be adopted in the treatment of the wound. Without this, it is not unattended by danger of septic changes in the thrombus followed by pyæmia. It is conveniently done by making a small longitudinal wound about one inch long, in which the vein may be exposed. Two ligatures either of prepared catgut or carbolized silk may then be applied, and the piece of vein between them cut out with scissors.

2. It has been recommended by Mayo, Sentin, Bonnet, and others, to *excite inflammation in the vein* by producing a series of deep eschars or issues in the skin, covering it by the application of a caustic, but such treatment has, very properly, been long abandoned.

3. *Coagulation of the blood in the vein by electrolysis* has also been recommended. A harelip pin is passed under the vein, and a twisted suture applied over it. Two insulated needles are then passed into the dilated vein below the pin, and a galvanic current of sufficient strength passed through them. The vein soon becomes filled with clot, and hard. After a few hours, when the danger of embolism is past, the pin may be removed. This plan has been tried at University College Hospital, but seemed to present no special advantages.

4. *Injection of the varix by a few drops of a solution of the perchloride of iron*, as recommended by Pravaz, is a very effectual method of procuring coagulation of the contained blood and consolidation of the varix, more particularly if it be very large and sacculated. In employing this means, it is essential to compress the vein by means of a tourniquet applied above the varix, which must not be removed till half an hour at least after the operation, for fear of embolism; the solution is then to be injected in very small quantity—not more than three or four drops—by means of the syringe (Fig. 425) into the dilated veins. Coagulation of the blood immediately takes place. The patient must be confined to his bed for a few days with the limb raised, and a bandage should be applied before he is allowed to walk about. This mode of treatment is very effectual in large varix, and may in such cases be advantageously combined with the next method—the pins being used under the venous trunks, and the solution introduced into the dilated masses of the varix. But it is not devoid of danger; accidents, such as local suppuration and sloughing, pyæmic symptoms, and even fatal embolism, have followed its use.

5. The most convenient and safest way of obliterating the vein in my opinion, and that which I always employ, consists in *compressing the vessel at several points*, by passing a harelip pin underneath it, laying a piece of wax

bougie over it, and then applying the twisted suture around the pin and over the bougie (Fig. 424). In this way the vessel gradually ulcerates by the pressure that is exercised upon it, and the presence of the bougie prevents the ligature from injuring the skin. In performing this operation, care must be taken that the vein be not transfixed, but that the pin be pushed, or rather dipped underneath it; the ligature should not be too thin, and must be applied

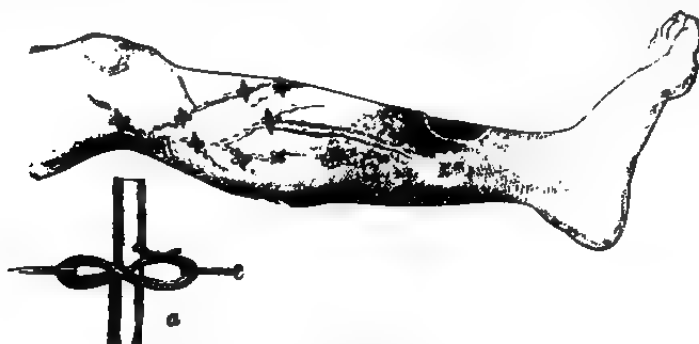

Fig. 424.—Application of Harelip Pins to Varicose Veins.

tightly over the bougie; several pins, as many as eight or ten, if necessary, should be introduced along the course of the same vessel, at distances of about three-quarters of an inch from one another (Fig. 424); those highest up should be put in first, and they should be left in for at least a week or ten days, by which time the obliteration of the vessel will have taken place. I believe that all the danger of the operation consists in the transfixion of the vein by the pin; the operator may always know when he has done this by the escape of a few drops of venous blood; when the pin is properly passed under and clear of the vein, the operation is a perfectly bloodless one. If the vein be transfixed, the pin should immediately be withdrawn and passed at another point; if it be allowed to remain in the vein, it will act as a foreign body, and septic changes in the thrombus may ensue. When the vein is properly compressed between the pin below and the bougie above, it becomes safely obliterated at the point of pressure. By attention to these circumstances I have never met with any ill-consequences, either from phlebitis or pyæmia, in any of the cases in which I have performed this operation, which are several hundreds in number.

In addition to the application of the pins in the usual way, H. Lee has recommended the subcutaneous division of that portion of the vein which is included between them, after coagulation of the blood has taken place. This I have found to be a useful addition to the ordinary treatment, and to insure the obliteration of the vessel.

The points of the pins may be prevented from pressing injuriously upon the skin, by putting small pieces of adhesive plaster under them. Whilst the pins are in, the patient must not be allowed to move about, and after they have been taken out, the limb should be bandaged for some time. In general, no ulceration takes place about the pinhole apertures; but occasionally, in debilitated constitutions, a sore forms, which requires to be treated on ordinary principles.

CHAPTER XLI.

ANEURISM BY ANASTOMOSIS, AND NIEVUS
HEMORRHAGIC DIATHESIS

ANEURISM BY ANASTOMOSIS.

Aneurism by Anastomosis is a disease of the arteries in which the vessels become excessively elongated, tortuous, and serpentine; sometimes they assume a varicose condition, being dilated into small anuses, and are always very thin-walled, resembling rather veins than arteries in structure. This kind of dilatation of the vessels gives rise to pulsating tumors, often of considerable size, and of a very active and dangerous character. They may be situated in almost any tissue or organ of the body, but are generally situated in the subcutaneous and subcutaneous areolar tissue, and most frequently in the upper part of the body, especially about the scalp, orbit, lips, and face; but they have been met with in other situations, such as the tongue, and even in internal organs, as the liver; and I have seen very active growths of this kind on the side of the chest, nates, and foot. It will generally be found that the arteries leading to an aneurism by anastomosis, though at a considerable distance from it, are tortuous and enlarged, with thin and expanded coats, and pulsate actively; in fact, constituting that condition which goes by the name of **Circoid Dilatation** of the vessels.

Aneurism by anastomosis forms tumors of varying magnitude and irregular shape; they are usually of a bluish color, have a spongy feel, are readily compressible, not circumscribed, and have large tortuous vessels running into and from them on different sides. Their temperature is generally above that of neighboring parts; and a vibratory or purring thrill, with distinct pulsation may be felt in them. This pulsation or thrill is synchronous with the heart-beat, may be arrested by compressing the tumor or the arteries leading to it, and returns with an expansive heat on the removal of the pressure. The bruit is often loud and harsh, but at other times of a soft and blowing character. These growths rarely occur in infancy, but generally make their appearance in young adults, though they may be met with at all periods of life, often as the consequence of injury.

DIAGNOSIS.—It is of importance to effect the diagnosis between *ordinary aneurism* and that by anastomosis. In many cases the situation of the tumor at a distance from any large trunk, as on the scalp, the outside of the thigh, or the gluteal region, will determine this. Again, the outline of the growth is less distinct than in true aneurism; and tortuous vessels will be felt leading to it from different directions. The swelling also is doughy and very compressible; but, when the pressure is removed, the blood enters it with a whizzing thrill, not with the distinct pulsating stroke that is found in aneurism. The pulsation, not so forcible as in aneurism, is more heaving and expansive. The bruit is louder, and more superficial, sometimes having a cooing tone. If we are on the arteries leading to the tumor these signs are usually not arrested, though diminished in force, the blood entering it from the neighboring parts, and in a less direct way.

TREATMENT.—The treatment of aneurism by anastomosis must depend upon the size and situation of the growth. When it is so placed that it can be *ligatured* or *excised*, as on the lip, or when small, about the neck, face, or scalp, trunk, or extremities, it should be removed. I always prefer the ligature, applied as will immediately be described, as being the safest, and upon the whole the readiest mode of removing such a tumor. If excision be practised, it is necessary to be very careful to cut widely of the disease; if it be cut into, fearful hemorrhage may ensue, which can only be arrested by pressure, and which in several instances has proved fatal.

If the disease be very large and extended, as is commonly seen on the scalp, or if deeply seated, as in the orbit, neither ligature nor excision of the tumor can be practised, and it becomes necessary to starve it by cutting off its supply of blood. This may be done either by *ligaturing the principal branches leading to it*, or *the main trunk of the limb or part*.

Simple ligature of the *arterial branches leading to the tumor* has never, I believe, been followed by success; at least, in ten recorded instances in which it has been had recourse to, the disease has not in one instance been cured. It has, however, been successfully conjoined by Gibson, in two cases of aneurism by anastomosis of the scalp, with incisions made round the tumor at intervals between the principal feeding arteries, which at the same time were tied.

The *main trunk* leading to the tumor has been ligatured in a considerable number of cases. The brachial and femoral arteries have been tied for disease of this kind situated on the extremities, and in some instances with success; but the carotid is the vessel that has been most frequently deligated, in consequence of the tumor being commonly situated on the scalp and in the orbit. Wyeth has collected 98 cases in which the carotid was ligatured for vascular growths above the clavicle, and excluding cases of "intraorbital aneurism." The results have not been encouraging; in 73 cases in which the common carotid was tied, almost 30 per cent. died directly from the operation, and about 50 per cent. only of those that recovered derived any benefit from the operation. Both common carotid arteries were tied at varying intervals in 9 cases, of these 2 died, 1 was cured, 2 improved, and the rest recovered, but derived no benefit from the operation.

In many of the cases in which one carotid alone was tied, the disease, being seated upon the scalp, was not cured; and it was afterwards found necessary to have recourse to ligature of the tumor, to excision, and to other means of removal; indeed, when seated upon the scalp, this disease appears to be more intractable than in any other part of the body, owing probably to the freedom of the arterial supply from the numerous vessels that ramify in this region. Here, however, much benefit might be derived after ligature of the carotid, by adopting the plan suggested by Gibson of tying the feeding arteries, and making incisions between them down to the bone. The ligature of the carotid has answered better for pulsating tumors in the orbit, but few of these are true cirroid aneurisms. (See Intraorbital Aneurisms.)

NÆVUS.

This disease, under which are included those various affections termed *Mother's Marks*, *Erectile Tumors*, and *Vascular Growths*, constitutes an important and interesting section of surgical affections.

Nævi are commonly divided into two chief varieties, capillary or cutaneous, and venous, cavernous, or subcutaneous. Aneurism by anastomosis was formerly included under the name of arterial nævus. The simple capillary nævi are composed merely of the capillary vessels of the skin greatly

increased in size and number; the cause of their growth is quite unknown. Venous or cavernous naevi are usually definitely circumscribed tumors, composed of spaces lined with an endothelium similar to that of the veins and bounded by a thin wall. The whole mass is bound together by a delicate areolar tissue. The spaces are filled with dark venous blood. The arterial supply is usually small, the arteries open directly into the spaces, without the intervention of capillaries. These naevi are sometimes purely subcutaneous, but more commonly implicate the skin. The most common condition is to find the two forms of naevus conjoined, the disease assuming the capillary form in the skin and the venous beneath. In some cases the subcutaneous naevus is not clearly defined, but consists of a mass of tortuous, thin-walled veins, surrounded by a considerable quantity of areolar tissue, sometimes containing fat. In fact, the structure of the various naevoid growths differs considerably in different cases, and the various forms merge into each other. (See also *Angiomata*, vol. i. p. 453.)

Naevi are almost always, if not invariably, congenital. Cavernous naevi occasionally seem to appear in young adult life, but it is probable that these were originally of congenital origin, and commenced active growth at an unusually late period. Naevi are not associated, except accidentally, with any other congenital defect.

Capillary Naevi appear as slightly elevated but flat spots on the skin, of a bright red or purple tint, and having occasionally granular or papillated elevations, with some larger vessels ramifying on their surface. They often spread superficially to a considerable extent; they are usually situated on the face, head, neck, or arms, but occasionally, though more rarely, on the back, the nates, the organs of generation, and the lower extremities. They are often at birth very small, not larger than a pin's head, from which they may spread in the course of a few weeks or months to patches an inch or two in diameter. In many cases no inconvenience results from this disease, except the deformity it causes; but occasionally, more especially when the growth is at all prominent, there is a great disposition to unhealthy ulceration. When bleeding occurs from a wound of the naevoid structure it is usually in a trickling stream, and without any degree of force.

Venous or Cavernous Naevi are of a dark purple or reddish color, usually very prominent, and often forming distinct tumors of considerable size, which may either be smooth and ovoid, or somewhat lobulated. On compressing a growth of this kind, it subsides to a certain extent, feeling doughy, soft, and inelastic; and on the removal of the pressure fills again. In some cases, when consolidated by inflammation, or containing cysts, they cannot be lessened in bulk by pressure. These naevi are usually of about the size of half a walnut, but sometimes much larger. I have removed from the nates and the back, some quite as large as an orange. They occur less frequently upon the head and face than the capillary form of the disease; most of the instances that I have seen have been met with in the lower part of the body, about the nates, back, lower extremities, and organs of generation.

When a venous naevus is purely subcutaneous, it forms a soft, doughy tumor, often clearly defined in outline. Its most characteristic feature is that it can be diminished by pressure, on the removal of which it slowly fills out again to as large a size as before; it also becomes distended when the child screams or struggles. It is usually oval, smooth, and uniform in outline. Occasionally the surrounding veins are bluish and enlarged.

Cysts are sometimes found in naevi containing a dark fluid. They result from obliteration of the communication between some of the spaces of the naevus and the vessels which carry off the blood. The tumors once supposed

to be consolidated nævi, with cysts scattered through them containing clear fluid, are now regarded as of lymphatic origin.

PROGNOSIS.—The natural history of nævi has yet to be learnt—we have yet to ascertain what becomes of them when left to themselves. They are so commonly removed by operation, that hitherto Surgeons have had but few opportunities of determining this. I have, however, seen several cases in which from various circumstances no operation had been performed, and I have been struck with the tendency that there is in the cutaneous nævus to disappear. If left untouched, or subjected to continuous pressure, islands or patches of white skin will gradually appear on the reddened surface. These will slowly increase and coalesce, and then the nævus, becoming gradually less vascular, may in time disappear. Subcutaneous venous nævi will sometimes gradually shrink, but the active erectile nævus is progressive.

There is usually a fear expressed of nævi, if left without surgical interference, leading to dangerous or even fatal hemorrhage. This I have never seen; indeed, if the nævus ulcerates its tissue hardens, and the vessels become blocked up by coagulum, and hence less disposed to bleed.

TREATMENT.—In the treatment of nævus, the first point to be determined is whether the case should be left to nature, or whether operative measures should be had recourse to. In deciding this point we must be guided by the size, situation, and character of the morbid growth. If this be small, cutaneous, and superficial, so situated that it occasions little or no disfigurement, and if it show no tendency to increase, it may be left without interference; when, as just stated, it may eventually shrivel and disappear, or become converted into a kind of mole. In some cases this process may be hastened by the application of tincture of iodine or liquor plumbi. In other cases, again, the nævus, though cutaneous and superficial, is so widely diffused over the surface, that no attempt at its removal or destruction can be entertained with prudence. But, if the nævus be large, if it be subcutaneous, or if it increase in size, or if it be so situated as to occasion disfigurement, means must then be adopted for its removal by operative procedure.

Operations for the removal of nævi may be conducted on six principles: 1, to excite adhesive inflammation in them, and so to produce plugging and obliteration of the vascular tissue of which they are composed; 2, to destroy the growth by caustics; 3, to remove it by the cautery; 4, to consolidate it by electrolysis; 5, to remove it with the knife; or, 6, to remove it by ligature. Each of these different plans of treatment is peculiarly applicable when the disease assumes certain forms and affects certain situations.

1. When the nævus is of small size, and occurs in such situations that its destruction by caustics, or removal by knife or ligature, would be attended by serious deformity, as when it is seated about the eyelids, upon the tip of the nose, at the inner angle between the eye and the nose, or about the corners of the mouth, it is best to endeavor to procure obliteration, by exciting inflammation in it. This may be done in various ways. If small, the nævus may be vaccinated. If it be larger, the most convenient plan consists, perhaps, in passing a number of fine silk threads across the tumor in different directions, and leaving them in for a week or two at a time, until they have produced sufficient inflammation along their tracks, then withdrawing them and passing similar threads into other parts of the tumor. In this way its consolidation may gradually be effected. Another very useful plan is to break up the substance of the growth subcutaneously by means of a cataract-needle, or tenotome, and, in the intervals between the different introductions of this instrument, to keep up pressure upon the tumor. In other cases,

again, the requisite amount of consolidation will be induced by passing acupuncture-needles into the nevus, and then heating them by means of a spirit-lamp. Perhaps the most efficient way of attaining this object is by injecting the perchloride of iron by means of a small glass syringe with a

Fig. 425.—Syringe for injecting Nevus.

screw-piston rod and a fine, sharply pointed platinum nozzle (Fig. 425). In doing this, care must be taken that but a very small quantity of the solution, not more than two or three drops, be injected at one time. The perchloride of iron possesses extraordinary power of coagulating the blood; and, if more than has just been mentioned be thrown in, the tissue of the nevus may either have its vitality destroyed, and slough, or coagulation of the blood in the vessels beyond the nevus may occur, and a dangerous or even fatal embolism ensue from the coagulum thus formed being washed into the current of the circulation. In order to prevent this latter accident, a tourniquet should be placed on a limb if it be the seat of the nevus. If the nevus is seated on any other part, it is better to pass two hairpin pins beneath it, and apply a temporary ligature beneath the pins during the operation; this can safely be removed after about a quarter of an hour. If preferred, tannic acid dissolved in water in the proportion of $\frac{1}{2}$ to $\frac{3}{4}$, as recommended by Bryant, or a few drops of a strong solution of chloride of zinc, may be injected instead of the perchloride of iron.

2. When the nevus is small, very superficial, of the capillary character, with an exceedingly thin covering of cuticle, and so situated, as upon the arm, neck, or back, that a moderate amount of scarring is of little consequence, it may most conveniently be removed by the *free application of nitric acid*. This should be well rubbed on by means of a piece of stick. The skin round the nevus may be greased to prevent its being accidentally touched by the acid, and as soon as the caustic has been sufficiently rubbed in, it may be neutralized with some carbonate of soda. After the separation of the slough, its application must be repeated as often as there is any appearance of prominent granulations springing up, which occasionally happens at one angle of the wound, and indicates a recurrence of the vascular growth.

3. The *actual cautery* has been largely used in the treatment of nevi, and is extremely convenient and efficacious in many cases. It is most applicable to mixed cutaneous and subcutaneous nevi. It may be used as the galvanic cautery or as Paquin's thermo-cautery. The heated platinum wire or the pointed cautery in Paquin's apparatus is made to puncture the growth round its margin, leaving about a quarter of an inch between the separate punctures. Each should extend well into the subcutaneous portion of the tumor. A number of other punctures are then made into the tumor in the central part care being taken not to make too many, lest the whole mass slough. In this way a large nevus can often be destroyed with comparatively little loss of skin, a smooth white scar being left. It is often necessary to repeat the operation more than once before a cure is effected. After the operation tannic acid ointment or some other simple dressing must be applied.

4. *Excision*, or *removal by surgery*, is best adapted to those cases of deep-seated nevi in which the treatment is difficult, or to those so situated as to make it impossible, if possible, to save the skin. The operation is performed

by passing into the naevus two needles, insulated except for the last quarter of an inch, by a coating of copal varnish, and then connecting them with a galvanic current of moderate strength from one of the ordinary medical batteries. The current should be gradually increased and the effect watched. The tumor becomes hard somewhat suddenly, and assumes a pale or almost white tint; this is a sign that enough has been done. The moment the earliest sign of hardening appears the needles should be disconnected, and connected with the opposite poles of the battery, so that the needle which was negative becomes positive. By doing this hemorrhage is prevented when the needles are withdrawn, as the salts of iron formed by solution of the end of the positive needle serve as an efficient hæmostatic. If gas bubbles out alongside the needles it is a sign that the current is too strong, and some cells should be taken off, or sloughing may result. In deep-seated nævi the effect can be judged of only by the hardening of the tumor. The operation has often to be repeated several times before the naevus is finally cured.

5. When the naevus is large, constituting a more or less distinct tumor, and is of a somewhat venous character, it may occasionally be excised. Pridgin Teale has shown that some nævi which are distinctly encapsuled may readily be dissected out. Should the naevus, however, be diffused, without any distinct limiting capsule, care should be taken to cut wide of the disease; and no operation with the knife should be undertaken unless the growth be either so situated, as upon the lip, that the parts may readily be brought or compressed together, or upon the nates or thigh, where it is unconnected with large bloodvessels, and is also very indolent and venous. It is especially when the naevus is lipomatous or cystic, or is distinctly encapsuled, that excision may be advantageously practised.

6. As a general rule, it is far safer and more convenient to extirpate the growth with the *ligature*; and this, indeed, is the mode of treatment that is most generally applicable to tumors of this kind in whatever situations they may occur, as it effectually removes them without risk of hemorrhage, and leaves a sore that very readily cicatrizes.

The ligature requires to be applied in different ways, according to the size and situation of the tumor. In all cases, the best material is firm, round, compressed whip-cord. This should be tied as tightly as possible, and knotted securely, so that there may be no chance of any part of the tumor escaping complete and immediate strangulation. It is well, if possible, not to include in the noose any healthy skin, but to snip across with a pair of scissors that portion of integument which intervenes between the cords that are tied together; at the same time, care must be taken to pass the ligatures well beyond the limits of the disease.

When the tumor is small, an ordinary double ligature may be passed across its base, by means of a common suture-needle; and, the noose being cut and the thread tied on each side, strangulation will be effected. When it is of larger size, and of round shape, the most convenient plan of strangulating the tumor is that recommended by Liston. It consists in passing, by means of long naevus-needles, fixed in wooden handles, and having their eyes near their points, double whip-cord ligatures in opposite directions across the tumor; then cutting through the nooses, and tying together the contiguous ends of the ligatures until the whole of the growth is encircled and strangled by them. In doing this a few precautions are necessary: thus, the first naevus-needle should be passed across the tumor unarmed (Fig. 426), and used to raise up the growth somewhat from the subjacent parts. The second needle, armed as represented in the diagram (Fig. 426), carrying the whip-cord ligature by means of a piece of suture-silk, should be passed across the tumor in the opposite direction to, but underneath, the first needle; the

armed needle being withdrawn, the ligature is carried across; and the first one, having been armed in the same way, carries its noose through the tumor as it is drawn out. The two nooses having then been cut, an assistant must seize, but not draw upon, six of the ligature ends; the Surgeon then, having

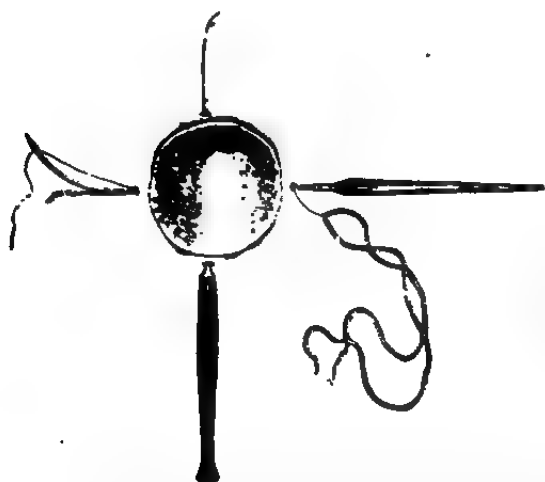

Fig. 426.—Diagram of the Application of Navus-needles.

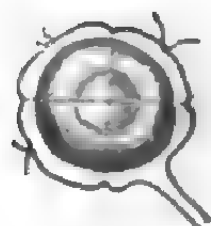

Fig. 427.—Diagram of Navus tied.

divided the intervening bridge of skin, ties rather tightly, in a reef-knot, the two ends that are left hanging out; as soon as he has done this, he proceeds to the next two, and so on to the last (Fig. 427). When he ties these, he must do so with all his force, especially if the tumor be large, as by drawing on them he tightens all the other nooses, and drags the knots towards the centre of the growth, which is thus effectually strangled. He then cuts off the tails of the ligature. The strangulated navus may be punctured to diminish the size of the sloughing mass, and then powdered with iodoform and dressed with dry cotton-wool, the dressing being left on till the slough separates. After the tumor has sloughed away, which happens in a few days, if it be properly and tightly strangled, the wound is treated on ordinary principles. If the navus be altogether subcutaneous, the skin covering it should not be sacrificed, but, being divided by a crucial incision, may be turned down in four flaps, and the ligature then tied as directed.

In some cases, the navus is so flat and elongated that the application of the quadruple ligature, as above described, cannot include the whole of it. In these circumstances, I have found the ligature about to be described eminently useful, having successfully employed it in a great number of instances. Its great advantage is that, while it completely and very readily strangles the tumor, it does not enclose an undue quantity of integument, and thus does not produce a larger cicatrix than is necessary for the eradication of the growth. It is applied in the following way: A long triangular needle is threaded on the middle of a piece of whipcord about three yards in length; one-half of this is stained black with ink, the other half is left uncolored. The needle is inserted through a fold of the sound skin, about a quarter of an inch from one end of the tumor, and transversely to the axis of the same. It is then carried through, until a double tail, at least six inches in length, is left hanging from the point at which it entered; it is next carried across the base of the tumor, entering and passing out beyond its lateral limits, so as to

leave a series of double loops about nine inches in length on each side (Fig. 428). Every one of these loops should be made about three-quarters of an inch apart, including that space of the tumor; and the last loop should be brought out through a fold of healthy integument beyond the tumor. In this way we have a series of double loops, one *white*, and the other *black*, on each side (Fig. 428). All the *white* loops should now be cut on one side, and the *black* loops on the other, leaving hanging ends of thread of corresponding colors. The tumor may now be strangulated by drawing down and knotting

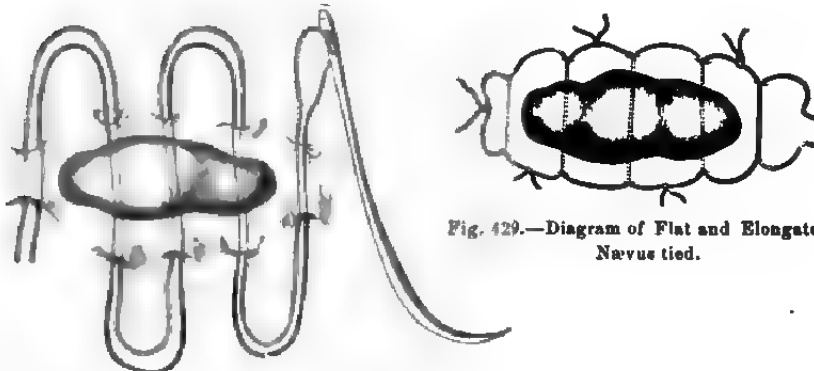

Fig. 428.—Diagram of Ligature of Flat and Elongated Nævus.

Fig. 429.—Diagram of Flat and Elongated Nævus tied.

firmly each pair of *white* threads on one side, and each pair of *black* ones on the other. In this way the tumor is divided into segments, each of which is strangulated by a noose and a knot; by *black* nooses and *white* knots on one side, by *white* nooses and *black* knots on the other (Fig. 429).

The cicatrix resulting from the removal of a nævus is usually firm and healthy; but, in some instances, I have seen it degenerate into a hard warty mass requiring subsequent excision. The ligature may be used successfully at all ages. I have repeatedly tied large active nævi in infants a month or two old without meeting with any accident.

In some situations in which it is very desirable to save the skin, the nævus may often be cured by *subcutaneous ligature*. This is done by passing a curved nævus-needle armed with a strong silk ligature as far as possible round the growth, immediately beneath the skin; on the eye emerging the thread is secured and the needle withdrawn. The needle is then passed unarmed so as to include the other half of the tumor; as soon as its eye appears it is threaded with the end of the ligature and drawn back. The ligature is then tightened, and the nævus thus strangulated subcutaneously. If preferred, the operation can be done with a common suture needle, which can be withdrawn and reinserted where necessary without being rethreaded. The silk ligature separates by suppuration after a week or ten days.

Attempts have been made to apply subcutaneous ligatures of carbolyzed silk or catgut, and then to push the knot in at the needle-puncture, leaving the thread to be absorbed. This method has not, however, been very successful, as either the ligature excited suppuration and was finally expelled, or after its absorption a return of the growth took place.

Widely diffused capillary nævi admit of but little treatment. Various attempts have been made to diminish the disfigurement by the application of superficial caustics, but the results of this treatment are not satisfactory.

Balmano Squire has recommended scarification of the surface with an in-

strument composed of a number of very fine knife blades set closely together, and from this some benefit has resulted.

NAVI IN SPECIAL SITUATIONS.—**Nævi of the Scalp** are more frequent than in any other situation, except, perhaps, the face. When occurring on those parts that are covered by hair, they are almost invariably prominent and subcutaneous; when seated on the forehead, or on the bare skin behind the ears, they are often cutaneous. The ordinary subcutaneous nevus of the scalp is readily removed by the application of the *quadruple ligature*. Care must be taken in passing the needles not to include the tendon of the occipito-frontalis, or troublesome cellulitis and, perhaps, suppuration may occur beneath that membrane. In general, it is better not to attempt the preservation of any of the integument covering the growth. It is true that, when removed, a clean white cicatrix is left which never covers itself with hair; but this contracts, and in after life becomes but little visible. The attempt to dissect down the skin that covers the nevus is not only troublesome, but is attended by very considerable and possibly dangerous hemorrhage. Those flat naevi that are situated behind the ear are best treated by the free application of fuming nitric acid, or Paquelin's cautery.

Nævus of the Fontanelle is the most important variety of the scalp-nevus, and constitutes a somewhat formidable disease. A large purple tumor is situated over the anterior fontanelle, rising and falling with the pulsations of the brain communicated to it, and becoming distended and tense when the child cries. The tumor is evidently close upon the membranes of the brain, and this often deters practitioners from interfering with it, and I have not unfrequently seen cases in which the parents of the child have been counselled not to allow any operation to be practised, lest death should result. Yet this tumor, so formidable in appearance, and so deeply seated and close upon the brain, may be removed with perfect safety by the *ligature*. I have often tied naevi in this situation, and have never seen any ill-consequences, not even a convulsive fit, occur. The danger, then, from the mere strangulation of the tumor in this situation cannot be great; but there is another and a special danger, viz., the risk of wounding the membranes of the brain in passing the ligatures under the base of the tumor. If *navus-needles* or sharp-pointed instruments of any kind be used, this accident will be very likely to occur; and, if this were to happen, inevitably fatal consequences will ensue. This accident may always be avoided by operating in the following way. A puncture is made in front of the tumor through the healthy scalp. An eyed probe, armed with a double ligature, is then pushed through this opening across the base of the tumor, and its end is made to project on the opposite side beyond it; here another puncture is made, and the probe and ligature together are drawn through. The same procedure is adapted across the tumor sideways. In this way, a quadruple ligature is passed across the tumor in two opposite directions: the ends are then disengaged, and the ligature is tightened in the ordinary way.

Nævi of the Face are of very common occurrence, and usually cause much disfigurement. The treatment to be adapted necessarily varies greatly, according to the nature of the nevus, whether cutaneous, subcutaneous, or both, and especially according to its situation. The same point, which is advantageously adapted in one part, may be altogether inadvisable in another. We shall, accordingly, consider the treatment of these vascular growths, as they affect the eyelids, the nose, the cheeks, and the lips.

Nævus of the Eyelids is usually cutaneous, consisting of a discoloration or staining, as it were, of the lid, without any material swelling. Such a disease as I think, better left untouched, it cannot, of course, be removed either by the knife or by caustics, without producing worse results; and, as

the skin is always deeply involved, milder means are inoperative, or possibly equally destructive. I have heard of sloughing of the eyelid being occasioned by the use of astringent injections; though, if the nævus were subcutaneous and constituted a distinct tumor, passing perhaps into the orbit, destruction of the growth by electrolysis is the safest and most efficient mode of treatment.

Nævus of the Nose may occur in two situations—at the root, or towards the alæ and apex. When seated at the root of the nose, upon the bridge, or at the lower part of the forehead, between and perhaps extending above the eyebrows, it is often subcutaneous, and may attain a very considerable magnitude. In cases of this kind, I have found the *quadruple ligature* the readiest means of removal; and although the part included may be of large size, the resulting cicatrix is wonderfully small and narrow, usually becoming horizontal, so as to fall into the folds of the skin naturally existing in that situation. In the case of a little girl about three years of age, under my care some few years ago, I removed a nævus that was cutaneous as well as subcutaneous, and as large as a walnut, from this situation, by means of the quadruple ligature, with the most satisfactory result, the resulting cicatrix being remarkably small; and in another little girl, from the bridge of whose nose I removed, some years ago, a nævus as large as a marble, very little scarring or deformity resulted. In both these cases, the nævus was cutaneous as well as subcutaneous. If the skin be not affected, the application of a temporary ligature followed by injection of perchloride of iron may be advantageously employed, or the growth may be destroyed by electrolysis. When the tip and alæ of the nose are affected, the nævus being cutaneous, we can seldom do much to improve the appearance of the patient. In such cases, I have tried breaking down the nævus, and the galvanic cautery, without any material benefit; the destruction of the tissues soon afterwards leading to deformity. When the nævus is subcutaneous, occupying the tip, alæ, and column nasi, galvano-puncture, or injection with perchloride of iron, are the only means that I have found of real service. If the perchloride be injected, care must be taken not to throw in too much of the liquid, lest sloughing or sudden death result.

Nævi of the Cheeks may occur in three distinct forms. 1. There may be a simple cutaneous nævus, a mere staining of the skin, a "mother's mark." This admits of no satisfactory treatment in most cases; and the subject of it must submit to continue through life to exhibit the characteristic discoloration. 2. The elevated cutaneous nævus may be raised above the surface, being of a deep purplish-red or plum-color, and covered with a very thin integument. In this form of the disease, I think that the application of concentrated nitric acid is the best means of extirpation. By one or two free applications of the caustic, the growth is removed, and a dense white cicatrix, presenting little disfigurement, is left in its place. 3. The nævus may involve the whole thickness of the cheek, being scarcely, if at all, cutaneous. Nævi of this kind cannot, of course, be extirpated, either by the knife, ligature, or caustics, lest the cheek be perforated, and the most serious disfigurement ensue. In such cases we must endeavor to obliterate the structure of the nævus by galvano-puncture, by exciting inflammation in it by setons, or by breaking down the structure of the growth with cataract-needles or a fine tenotome. In a case which I attended some years ago, I cured a large and deeply seated nævus, which occupied one cheek, by passing a number of fine silk threads across it in different directions, and gradually breaking it down piece by piece, with a cataract-needle; no disfigurement whatever being left.

Nævi of the Lips require different treatment, according as they occupy the margin or have involved the whole substance of those parts. When seated at the margin, as projecting and somewhat pendulous growths, they may very readily be removed by a double or quadruple ligature, according to their size. This was the practice pursued in the case from which the accompanying drawings (Figs. 430, 431) were taken, where a most excellent result was obtained by the use of the ligature, followed at a later period by injection of perchlo-

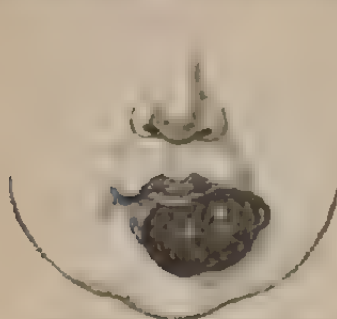

Fig. 430.—Nævus of Lower Lip:
Front View.

Fig. 431.—Nævus of Lower
Lip: Side View.

ride of iron into some of the more widely diffused parts of the growth. When the nevus involves the whole thickness of the lip, such measures are not always available. In these cases galvano-puncture, repeated at intervals of about a week till the whole growth is consolidated, is perhaps the safest and best treatment. The injection of perchloride of iron, tannic acid solution, or chloride of zinc, may effect a cure in most cases; but a temporary ligature should always be applied, and left on for about a quarter of an hour, to prevent any accident arising from the direct entrance of the styptic fluid into the blood-stream.

When the whole substance of the lip is involved, inclusion and strangulation of the morbid mass by means of ligature are seldom available; the

Fig. 432.—Large Nævus of Upper lip
Front View.

Fig. 433.—Large Nævus of Upper
Lip: Side View.

amount of sloughing being very great, and the child, absorbing the putrescent matters from the sloughing mass which results, incurring the danger of being poisoned from the source. In an infant with a very large nevus, including one half of the lip, which I ligatured at the Hospital some years ago, death

appeared to result from this cause. One of the most formidable cases of *nævus* of the lip that I have ever had to do with, and in its results the most satisfactory, was sent to me several years ago, by Budd, of Barnstable. The patient, a little girl five years old, was noticed at birth to have a red streak on the right side of the upper lip; this rapidly developed into a large tumid purple *nævus*, which, when the case came under my observation, was about the size of a large walnut, involving the whole of the structures of the lip, from the cutaneous to the mucous surfaces; it was of a deep mulberry color, and extended from the median line of the lip to the angle of the mouth (Figs. 432-434). The integuments covering this growth were exceedingly thin, and the tumor itself was in the highest degree vascular and active. Excision appeared to be out of the question; the ligature presented little to recommend it, injections with the perchloride of iron and the introduction of setons were successively tried, but neither of these means produced any effect on the tumor, which commenced to extend upwards into the nostril. I accordingly determined on using caustics. Nitric acid was first employed; but, as this did not produce sufficiently deep impression on the growth, I had recourse to the potassa cum calce. By means of this, the tumor was gradually removed; the hemorrhage which occasionally resulted being restrained by pressure. Notwithstanding the amount of tissue destroyed, the resulting cicatrix was small, resembling that of a badly united harelip. Three years afterwards the child was brought to me again, and I was much struck by the wonderful improvement that had taken place since the removal of the *nævus*. The lip was smooth, the cicatrix in a great degree worn out, and comparatively little disfigurement was left in the countenance of an exceedingly pretty and engaging child. Finding, however, that the lip was still drawn

or tucked in by a very dense band of cicatricial tissue, which caused a deep depression of the ala of the nose, on that side, I divided this, and the result was most satisfactory.

It has been recommended when the growth invades the substance of the lip deeply for a limited extent, to remove it by an operation somewhat similar to that for the removal of an epithelioma, the whole substance of the lip being cut through widely on each side, and the sides of the wound brought together with harelip pins. Such operations are, however, not advisable as apart from the danger of hemorrhage, the disease can always be cured by some of the means above described without leaving the amount of deformity that would result from its removal by the knife.

Nævus of the Tongue is of rare occurrence. I have, however, successfully operated by means of the *ceruseur* in one case, in which the whole of the free extremity of the organ was involved (Fig. 434). The particulars will be found in Chapter LIX.

Nævi of the Organs of Generation are occasionally met with in the female, but rarely in the male. The only instance of *Nævus of the Penis* with which I have met occurred in the case of a gentleman thirty-two years of age, who presented me some years ago for a growth of this kind, as large as a walnut, situated under the reflexion of the preputial mucous membrane. It had

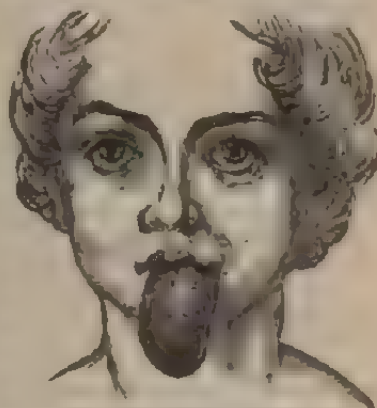

Fig. 434. - Nævus of Tongue.

existed for many years without giving any annoyance, but, as it had of late begun to enlarge, and occasionally to bleed, he was desirous of having it removed. This I did by applying the quadruple ligature, after having dissected the mucous membrane down.

Nævi of the Vulva are by no means unfrequent. We have had several instances of the kind in the Hospital of late years. They are usually venous, often attain a large size, and may sometimes involve the integumental structures on the inside of the thigh, or on the perineum, as well as the vulva. When the growth is confined to the vulva, it is best removed by the ligature. Some time ago, I removed in this way a large pendulous venous naevus, as large as two or three flattened walnuts, from the left labium of a little girl six years of age. In this case, I found it most convenient to employ the continuous ligature. The same means were had recourse to in order to extirpate a large naevus from the labium of a child three years of age, but in this case the disease extended to the integuments of the perineum and inner side of the thigh, and was here removed by the application of strong nitric acid, after the larger growth had separated.

On the Extremities, Neck, and Trunk every possible variety of naevus occurs. When the disease is flat, consisting rather of staining of the skin than of any actual tumor, it may commonly be treated successfully by the application of the strong tincture of iodine, or should it be thought desirable to remove it, this may be effected by rubbing it with strong nitric acid. If the naevus assume the form of a tumor, it will almost invariably be of a venous character, and then removal by extension by means of the ligature should be effected. If the growth be round, the ordinary quadruple ligature may be employed; if flat or elongated, the longitudinal continuous ligature is preferable.

NEVOID LIPOMA.—This is a form of naevus which I have occasionally seen, but which does not appear to have attracted much notice, although Nelaton speaks of it, and Billroth says that in lipoma he has several times met with cavernous dilatation of the veins. It is a tumor in which the nevus structure is combined with a fatty growth usually more fibrous than an ordinary lipoma. This disease is invariably seated upon the nates, back, or thigh. It occurs as a smooth, doughy, indolent tumor, incompressible, not varying in size or shape, without heat, thrill, or pulsation of any kind, possibly having a few veins ramifying over its surface, but no distinct vascular appearance. It is usually congenital, or has been noticed in early childhood; and it continues without any very material change in shape, size, or appearance, until the inconvenience or deformity occasioned by it requires its removal. This is best effected by the knife. After removal, the tumor will be found to be composed of a mass of fibrous fat, having a large number of veins ramifying through it, so as to constitute a distinct vascular element, often communicating with small cysts containing a bloody fluid. The tumor has occasionally a tendency to recur after removal. In one case I have operated three times for the removal of a large growth of this description, situated on the buttock, and extending forward towards the perineum. The first operation was performed in 1851; the second in 1856 and the patient, then eighteen years of age, again presented himself in 1863 with a new growth in an ulcerated state, in the cicatrix of the former one. The situation in which I have seen such tumors occur, where they rise to most inconvenience, and where their removal has required most care, has been the anterior part of the thigh, just below Poupart, close upon and almost in connection with the femoral vessels. Description, which was sent to me by Edwards, of Antigua, gentleman of that island, had suffered for some years from a

chronic solid œdema of one of his legs, apparently dependent upon the pressure exercised upon the saphena and femoral veins by an elongated indolent tumor just below Poupart's ligament, and over the course of these vessels. This tumor had existed from childhood, and presented the signs that have just been given as characteristic of the disease under consideration. It was removed by an incision parallel to Poupart's ligament, some careful dissection being required to separate it from the femoral sheath, more particularly towards the inner side, where a prolongation of the tumor dipped down by the side of the femoral vein, compressing that vessel, and thus causing the œdema of the limb. After removal, the tumor was found to consist of a mass of dense adipose tissue, with much vascular structure intermixed, and some small cysts. The œdema gradually subsided; and when the patient left England, about three months after the operation, the limb had nearly regained its normal size, being but little larger than the sound one.

HEMORRHAGIC DIATHESIS, OR HÆMOPHILIA.

In connection with diseases of the bloodvessels it may be stated that in some constitutional conditions it is found, though fortunately very rarely, that there is a great tendency to very troublesome, indeed almost uncontrollable bleeding, from slight wounds. An abnormal tendency to bleed is sometimes observed in persons who are "out of condition," and whose tissues are soft and flaccid. They bleed freely from slight wounds and bruise extensively from trivial blows. In these cases the bleeding appears to be maintained by the laxity of fibre preventing the proper contraction of the divided or torn vessels; and the tendency to hemorrhage will vary at different times in the same person according as the state of his health improves or deteriorates. In other cases abnormal bleeding may be due to a diminution in the normal coagulability of the blood. This state is sometimes met with in scurvy, chronic jaundice, and albuminuria. The disease known as Hemophilia or Hemorrhagic Diathesis is quite independent of such conditions as these. It is a peculiar constitutional state, always congenital, and most frequently hereditary, especially in the male line. In some families the males only have been affected, and the diathesis has been transmitted in the second or third generation through females; who, themselves being unaffected by it, have had male children who were the subjects of the disease. A very remarkable genealogical account of such a family has been drawn up by C. Heath. The diathesis occurs in persons without any other apparent derangement of health or morbid condition, innate or acquired, to account for it. In such cases the family peculiarity is usually recognized, and well known to those liable to it.

The only constant sign of the diathesis is the free and often almost uncontrollable bleeding that takes place from trivial wounds; life being put in jeopardy and even lost by the hemorrhage resulting from the extraction of a tooth, the opening of an abscess, lancing of the gums, or some equally slight unimportant surgical procedure. The blood does not flow in a jet, but continues to trickle in an oozing stream, apparently from the capillaries rather than from the larger vessels of the part. In these cases, also, there is a great tendency to inordinate ecchymosis from very slight contusion.

In these families of bleeders, it is scarcely necessary to say that it is imperative to be careful to make no surgical wounds, even of the most trivial character, if they can possibly be avoided. Above all, the extraction of teeth must be avoided. It is after this slight operation that the most uncontrollable and fatal hemorrhages have occurred. The hemorrhages, though usually traumatic, may be spontaneous; they then usually proceed from the nose,

1. The first part of the document discusses the importance of maintaining accurate records of all transactions and activities. It emphasizes that proper record-keeping is essential for transparency and accountability, particularly in financial matters. The text outlines various methods for organizing and storing data, including digital databases and physical filing systems. It also mentions the need for regular audits and reviews to ensure the integrity of the information.

2. The second section focuses on the role of communication in achieving organizational goals. It highlights the importance of clear and concise communication, both internally and externally. The text provides examples of effective communication strategies, such as regular team meetings, open-door policies, and the use of various communication channels like email, phone, and face-to-face interactions. It also discusses the importance of listening and understanding the needs and concerns of others.

3. The third part of the document addresses the challenges of managing a large and diverse workforce. It discusses the importance of providing training and development opportunities to help employees grow and improve their skills. The text also mentions the need for effective time management and prioritization to ensure that all tasks are completed efficiently. Additionally, it touches upon the importance of maintaining a positive and supportive work environment to boost morale and productivity.

4. The final section discusses the importance of staying up-to-date with industry trends and developments. It emphasizes that continuous learning and adaptation are crucial for long-term success. The text suggests various ways to stay informed, such as attending conferences, participating in workshops, and reading industry publications. It also mentions the importance of networking and building relationships with other professionals in the field.

TREATMENT.—In true hæmophilia no remedies appear to exercise the slightest influence over the diathesis. At the same time, it would be wise that the subject of this unfortunate condition should attend to those ordinary rules of health, the neglect of which, by lowering "his condition," might favor the tendency to bleed. Legg especially recommends the use of cold baths of plain, sea, or chalybeate waters, residence in a dry air, and the use of warm clothing. The preparations of iron are usually given in a routine way, but it is doubtful if they have ever been of service in preventing the hemorrhages, certainly never in arresting them, though they may be of use in removing the anæmic state left after a copious bleeding. Ergot has been given during the bleeding in many cases, but without evident effect.

The *Local Treatment* is that on which most dependence will necessarily be placed. It consists in the use of three means, viz., Pressure, Styptics, and Cold.

Pressure is to be relied on only in one form of hæmophilic bleeding—viz., the continuous hemorrhage from the socket of a tooth after extraction. In these cases the cavity should be cleared out and carefully plugged from the bottom by means of lint or agaric, the whole retained by means of a piece of cork and a gutta-percha cap to fit over the neighboring teeth, and compressed by a bandage applied under the chin against those in the sound jaw. When the hemorrhage occurs from the soft parts, pressure must be used with great caution lest sloughing occur; the integuments being extremely liable to give way extensively under very moderate pressure, large subcutaneous extravasation developing at the same time, and thus increasing materially the danger of the case and the local mischief.

Compression of the main artery of the limb is useless and liable to the objection of the development of ecchymoses and subcutaneous hemorrhages.

Styptics of all kinds have been used as a matter of course, and the perchloride of iron has enjoyed especial favor. I have used and seen it used frequently, and can safely say that I have never seen any permanent benefit from its application, or that of any other styptic, in these cases. Indeed, great evil has often resulted from the inflammation excited by the application of styptics of any kind. The parts become swollen, fall into slough, and as they separate the oozing may recommence from the raw surface, and the same process has to be gone through again.

The **actual Caustery** presents the same inconveniences as ordinary styptics. It may arrest temporarily the bleeding, but inflammation is set up in the parts beyond the limit of the eschar, and this on separating leaves an extended ulcerating surface which bleeds again, and perhaps more freely than before.

The continued application of **Cold** appears to arrest hæmophilic bleeding more effectually than any other means, and this circumstance would lead to the belief that the hemorrhage is due to want of contractility in the smaller arteries rather than to want of coagulability in the blood. The cold may be applied by means of irrigation of iced water, as has been done successfully by Marshall, or by the application of ice either directly to the part or laid upon a sponge covering it, as has been done in some of the cases of hæmophilia occurring at University College Hospital. Simple water may be used, or a weak antiseptic solution of boracic acid. If the bleeding wound be in the extremities, the limb should be elevated and kept at rest on a splint.

The Surgeon has already been cautioned as to the inexpediency of performing any operation, except under circumstances of the most urgent necessity, on any member of a family of bleeders, or on an individual known to be the subject of hæmophilia. Should an operative procedure become necessary, it should, if possible, be undertaken with Paquelin's thermo-cautery,

if it be desired to make a simple incision; by the galvanic *écraseur*, if it be expedient to remove a part or to perform a small amputation. In the event of the galvanic *écraseur* not being at hand, the *elastic ligature* would be the best substitute.

CHAPTER XLII.

DISEASES OF ARTERIES.

ARTERIES are liable to numerous diseases which derive great importance from the effects they produce, both upon the vessels themselves and upon the parts to which they carry the blood. Amongst the most important are the various forms of inflammation or arteritis. The inflammatory affections of arteries are divided first into two classes, viz., those resulting from injury, and those arising from general or local causes not of a traumatic nature. Inflammation of the arteries is divided also into endarteritis, in which it affects primarily or chiefly the internal coat, and peri arteritis, in which the process commences in the outer coat or sheath. The term mes-arteritis has also been suggested for inflammation of the middle coat, but it is of little use, as no true inflammatory affection commences in that part of the vessel. Some forms of arteritis are named from the cause of the disease, as syphilitic or embolic. As in other structures, the inflammatory process may be acute or chronic. In addition to the above diseases, arteries suffer from various degenerative changes, some of which are primary, affecting the original tissues of the vessels, others are secondary, the degeneration taking place chiefly in the products of a chronic inflammatory process. These various processes are still further complicated by secondary effects, such as the formation of aneurism, from the diseased walls of the artery yielding before the pressure of the blood, and thrombosis of the affected vessel followed by its obliteration, and sometimes by embolism and gangrene.

In discussing the diseases of arteries, it will be most convenient to consider first the various forms of inflammation; secondly, the degenerations; and lastly, the remoter effects of these changes.

ARTERITIS.

Acute Arteritis of idiopathic origin, that is to say, arising as an independent affection for which no evident cause can be found, was formerly believed to be a comparatively common affection. It was supposed to affect the inner coat, spreading along the vessel, in the direction of the circulation, and from this fact it was spoken of as diffuse or circumpetuous. It is now known, however, that no such affection really exists, and that the error arose partly from assuming that thrombosis is invariably evidence of previous inflammation of the affected vessel, and partly from mistaking for the redness of inflammation the staining of the intima, so often observed as the result of changes in the blood with disintegration of the red corpuscles, occurring either during life in acute forms of blood poisoning such as septicæmia or malignant fevers, or after death as the result of putrefaction.

Traumatic Arteritis.—Simple acute traumatic inflammation limited to the part injured and showing no tendency to extension, is familiar to every

Surgeon in connection with contusion, laceration, wound, or ligature of arteries; for in the early period of repair after any of these injuries, inflammatory exudation from the vasa-vasorum forms an essential part of the process. For a description of this condition, the reader is referred to vol. i. chap. xiv.

Arteritis by Extension, from infective inflammation or ulceration of the tissues surrounding the vessel, has already been described as one of the dangers accompanying these processes. In inflammation affecting an artery in this way, the process is the same as in other tissues. The vessels of the outer coat are dilated, inflammatory exudation with migration of corpuscles takes place, and the wandering cells infiltrate the coats of the artery, which become swollen and softened. The process spreads from the outer to the inner coat, the endothelium desquamates, and fibrin is deposited upon the diseased surface. In the smaller arteries complete thrombosis takes place, and the clot extends upwards to the nearest branch beyond the inflamed part of the vessel, and may then undergo the changes already described as occurring in the permanent closure of an artery (vol. i., Wounds of Arteries), and hemorrhage is thus prevented. In arteries above the size of the radial, however, the closure of the vessel is frequently not accomplished before the coats are so far softened as to give way before the pressure of the blood, and thus fatal hemorrhage may result. This is all the more likely to occur when the inflammation and subsequent ulceration affect a limited portion of one side only of the artery, as in those cases in which it is due to the contact of an irritating foreign body, such as a sequestrum. In the larger arteries complete thrombosis occurs much less readily than in smaller vessels or in veins, the rapidity of the flow of the blood being unfavorable to the adhesion of the white corpuscles, which is the first step in thrombosis.

In arteries which have been divided and secured by ligature or otherwise, the extension of unhealthy inflammation from the wound to the exposed end of the vessel, followed by softening of its coats, and disintegration of the contained clot, is the commonest cause of secondary hemorrhage.

Embolie Arteritis.—Moxon has pointed out that a form of acute arteritis, resulting in softening and swelling of the arterial wall, thus leading to the formation of an aneurism or to rupture of the vessel, is in rare cases the result of the lodgement of an embolus. A simple fibrinous embolus lodging in an artery merely obliterates the vessel without causing softening of its coats. In order that inflammatory softening may occur, it is necessary that the embolus should be derived from a part which is the seat of some infective inflammation, and that it should carry with it the unhealthy products of the process. Embolic arteritis is most likely to occur in the somewhat rare affection known as ulcerative or infective endocarditis, but it has also been known to follow embolism during the course of an ordinary case of acute rheumatism. Localized arteritis arising in this way is believed to be the most common, if not the sole cause of spontaneous aneurisms in children, and in the smaller vessels of the extremities in adults. Rushton Parker has recorded a case which well illustrates this form of disease. A boy, aged 14, during an attack of acute rheumatism was suddenly seized with pain in the forearm, followed by swelling of the limb. The general swelling soon subsided, leaving a deeply seated circumscribed tumor, which steadily increased in size for the next four months. On laying this open, a cavity was exposed containing more than a pound of dark clotted blood, and the anterior intercostal artery was found to communicate with it by an opening a quarter of an inch in length. The vessel was successfully ligatured above and below the opening, and the boy recovered. At the time of the operation there was a loud double aortic murmur.

Acute Endarteritis.—Cornil and Ranvier describe under this name an affection of the inner coat, met with chiefly in the aorta, but occasionally also in smaller vessels, especially near wounds. It is characterized, to the naked eye, by prominent patches formed by a swelling of the intima. They are circular or oval in outline, and seldom exceed half an inch in diameter, though both their form and size may be altered by the coalescence of neighboring patches. They are pale pink in color, and semi-transparent or opalescent; in consistence, they are soft and elastic, almost gelatinous. The internal surface has often lost its polish, in consequence of the irregularity of the swelling, but its endothelial covering is usually intact. The middle coat beneath the patch appears usually to be somewhat swollen, and this condition is more marked in the adventitia. Microscopic examination shows that the swelling is due to an accumulation of small cells, either round or slightly irregular in outline, between the fibres of the sub-endothelial connective tissue and the elastic layers of the inner coat. These cells have a distinct nucleus surrounded by a small quantity of protoplasm, and show signs of active growth. Cornil and Ranvier believe they are produced by proliferation of the original cells of the part. The swelling of the external coat is found to be due to the presence of numerous cells of new formation separating the fibres of the connective tissue.

The conditions under which acute endarteritis occur are not clearly determined, but as every intermediate condition between it and the chronic form to be immediately described, is to be met with, sometimes even in the same vessel, it seems to be nothing more than the same process increased in intensity.

Chronic Endarteritis, Arteritis Deformans, Atheroma.—This is by far the most common disease to which arteries are liable; in fact, it is very rare after middle life to find it completely absent in the larger vessels. It occurs in its most marked form in the aorta and the large arteries of the neck, abdomen, the upper parts of the limbs, and the base of the brain. It is less commonly seen in the smaller vessels, in which the muscular coat is more fully developed.

Chronic endarteritis first appears as pale yellowish patches or streaks, smooth, slightly elevated above the surface, and evidently seated in the deeper layers of the inner coat. They are irregular in outline, their long diameter is usually in the line of the vessel's course, but they show a special predilection for the mouths of the branches leaving the main trunk, round which they form annular elevations. Their outline becomes subsequently more irregular by the coalescence of neighboring patches. As the disease advances, the patches become more elevated, often reaching a line or more in thickness. At this stage they are grey, semi-transparent or opalescent, and inelastic, sometimes almost cartilaginous in appearance and consistence. This condition is, however, speedily followed, before the patches have reached more than half an inch in diameter, by a change to an opaque yellow color, the alteration in tint commencing in the central parts. This change is due to fatty degeneration, and is accompanied by some loss of toughness. The further progress may be in one of two directions; the growth may soften and break down, or it may cavity. When softening takes place the patch becomes converted into a pulsatous or cheesy mass, and even sometimes undergoes complete liquefaction into a yellow creamy fluid, which has been mistaken for true pus, and termed an "atheromatous mass." It is this change that led to the term atheroma being applied to the disease, the products of the softening of the patch resembling the contents of an atheromatous cyst of the skin. The term is now often extended to all stages of chronic endarteritis.

When the process reaches the more advanced stages the middle coat is

affected, first by chronic inflammation, and subsequently by softening. At the same time considerable thickening of the external coat takes place by the formation of dense fibroid tissue which is not prone to fatty degeneration and softening. Up to this stage the fatty patch is covered by the most internal layers of the intima and the endothelium, which are not affected by the chronic inflammatory process, but after complete softening these give way, and the atheromatous fluid is discharged into the circulation, leaving the remains of the patch exposed to the blood-stream. The raw surface thus formed is called "*an atheromatous ulcer*." The débris which enter the circulation are carried on and lodge in the capillaries, but not possessing any irritating properties they give rise to no evil consequences. Although on the formation of an atheromatous ulcer a considerable part of the inner and middle coats are lost, perforation or rupture of the artery rarely takes place, and it is only in exceptional cases that the blood forces its way amongst the coats of the diseased vessel. This is due to the fact that at the margins of the patch, the chronic inflammatory process has led to firm matting together of the coats of the artery. At the same time the thickening and induration of the external coat prevent perforation. It is especially opposite the deeper and more eroded atheromatous patches that this consolidation of the external coat takes place. The change, although described as a chronic inflammation, is strictly conservative in character. The new growth of fibroid tissue is not confined to the external coat, but extends to the sheath of the vessel, and, by soldering it to the contained artery, greatly adds to the strength of the vascular wall.

Although perforation is thus prevented, the new tissue but imperfectly represents the normal structures of the coats of an artery, as it is entirely wanting in elasticity. Consequently it is very apt to yield slowly to the pressure of the blood, and thus lead to the formation of a sacculated aneurism, the mouth of which will correspond to the damaged portion of the wall of the vessel.

Complete softening, with the formation of an atheromatous ulcer, is not by any means a necessary consequence of fatty degeneration of the patches resulting from chronic endarteritis. In many cases the new tissue, after degenerating, remains as a firm, yellow, opaque mass, and may undergo no further change, but most commonly lime salts are deposited in it, and it gradually becomes converted into a hard calcareous plate, over which the superficial layers of the inner coat with the endothelium may remain unbroken. Sometimes, however, these seem to wear away and the calcareous plate comes in direct contact with the blood-stream. This change was formerly described as "*ossification of the arteries*," but it need not be said that no true bone is formed. From the arrangement of the calcareous matter in plates corresponding to the atheromatous patches in which the lime salts have been deposited, this change has also received the name of *laminar calcification*.

Microscopic examination of an atheromatous artery in the early stage of the disease shows that the morbid change commences in the deeper layers of the inner coat by a proliferation of the flattened cells that lie between the laminae of connective tissue of which it is chiefly composed. The new cells are arranged in lines between the laminae. With the proliferation of the cells there is a growth of new laminae of connective tissue closely resembling that of the healthy inner coat, both in appearance and in arrangement. The change is therefore a true overgrowth of the deeper layers of the intima. The relative amount of cells and fibrous intercellular substance varies in different cases, but the chief bulk of the new tissue is always composed of the latter. The cells are small, rounded or slightly flattened, and

existed for many years without giving any annoyance, but, as it had of late begun to enlarge, and occasionally to bleed, he was desirous of having it removed. This I did by applying the quadruple ligature, after having dissected the mucous membrane down.

Nævi of the Vulva are by no means unfrequent. We have had several instances of the kind in the Hospital of late years. They are usually venous, often attain a large size, and may sometimes involve the integumental structures on the inside of the thigh, or on the perineum, as well as the vulva. When the growth is confined to the vulva, it is best removed by the ligature. Some time ago, I removed in this way a large pendulous venous nævus, as large as two or three flattened walnuts, from the left labium of a little girl six years of age. In this case, I found it most convenient to employ the continuous ligature. The same means were had recourse to in order to extirpate a large nævus from the labium of a child three years of age; but in this case the disease extended to the integuments of the perineum and inner side of the thigh, and was here removed by the application of strong nitric acid, after the larger growth had separated.

On the **Extremities, Neck, and Trunk** every possible variety of nævus occurs. When the disease is flat, consisting rather of staining of the skin than of any actual tumor, it may commonly be treated successfully by the application of the strong tincture of iodine; or should it be thought desirable to remove it, this may be effected by rubbing it with strong nitric acid. If the nævus assume the form of a tumor, it will almost invariably be of a venous character, and then removal by excision by means of the ligature should be effected. If the growth be round, the ordinary quadruple ligature may be employed; if flat or elongated, the longitudinal continuous ligature is preferable.

NÆVOID LIPOMA.—This is a form of nævus which I have occasionally seen, but which does not appear to have attracted much notice, although Nélaton speaks of it, and Blandroth says that in lipoma he has several times met with cavernous dilatation of the veins. It is a tumor in which the nœvoid structure is conjoined with a fatty growth usually more fibrous than an ordinary lipoma. This disease is invariably seated upon the nates, back, or thigh. It occurs as a smooth, doughy, indolent tumor, incompressible, not varying in size or shape, without heat, thrill, or pulsation of any kind, possibly having a few veins ramifying over its surface, but no distinct vascular appearance. It is usually congenital, or has been noticed in early childhood; and it continues without any very material change in shape, size, or appearance, until the inconvenience or deformity occasioned by it requires its removal. This is best effected by the knife. After removal, the tumor will be found to be composed of a mass of fibrous fat, having a large number of veins ramifying through it, so as to constitute a distinct vascular element, often communicating with small cysts containing a bloody fluid. The tumor has occasionally a tendency to recur after removal. In one case I have operated three times for the removal of a large growth of this description, situated on the buttock, and extending forward towards the perineum. The first operation was performed in 1851; the second in 1856 and the patient, then eighteen years of age, again presented himself in 1863 with a recurrence of the growth in an ulcerated state, in the cicatrix of the former operations. The situation in which I have seen such tumors occur, where they gave rise to most inconvenience, and where their removal has required the greatest care, has been the anterior part of the thigh, just below Poupert's ligament, close upon and almost in connection with the femoral vessels. In a case of this description, which was sent to me by Edwards, of Antigua, the patient, a gentleman of that island, had suffered for some years from a

chronic solid edema of one of his legs, apparently dependent upon the pressure exercised upon the saphena and femoral veins by an elongated indolent tumor just below Poupart's ligament, and over the course of these vessels. The tumor had existed from childhood, and presented the signs that have been given as characteristic of the disease under consideration. It was removed by an incision parallel to Poupart's ligament, some careful dissection being required to separate it from the femoral sheath, more particularly towards the inner side, where a prolongation of the tumor dipped down by the side of the femoral vein, compressing that vessel, and thus causing the edema of the limb. After removal, the tumor was found to consist of a mass of dense adipose tissue, with much vascular structure intermixed, and some small cysts. The edema gradually subsided; and when the patient returned to England, about three months after the operation, the limb had nearly regained its normal size, being but little larger than the sound one.

HEMORRHAGIC DIATHESIS, OR HEMOPHILIA.

In connection with diseases of the bloodvessels it may be stated that in some constitutional conditions it is found, though fortunately very rarely, that there is a great tendency to very troublesome, indeed almost uncontrollable bleeding, from slight wounds. An abnormal tendency to bleed is sometimes observed in persons who are "out of condition," and whose tissues are soft and flaccid. They bleed freely from slight wounds and bruise extensively from trivial blows. In these cases the bleeding appears to be maintained by the laxity of fibre preventing the proper contraction of the lacerated or torn vessels; and the tendency to hemorrhage will vary at different times in the same person according as the state of his health improves or deteriorates. In other cases abnormal bleeding may be due to a diminution in the normal coagulability of the blood. This state is sometimes met with in scurvy, chronic jaundice, and albuminuria. The disease known as Hemophilia or Hemorrhagic Diathesis is quite independent of such conditions as these. It is a peculiar constitutional state, always congenital, and most frequently hereditary, especially in the male line. In some families the males only have been affected, and the diathesis has been transmitted in the second or third generation through females; who, themselves being unaffected by it, have had male children who were the subjects of the disease. A very remarkable genealogical account of such a family has been drawn up by C. Heath. The diathesis occurs in persons without any other apparent derangement of health or morbid condition, innate or acquired, to account for it. In such cases the family peculiarity is usually recognized, and well known to those liable to it.

The only constant sign of the diathesis is the free and often almost uncontrollable bleeding that takes place from trivial wounds; life being put in jeopardy and even lost by the hemorrhage resulting from the extraction of a tooth, the opening of an abscess, lancing of the gums, or some equally slight unimportant surgical procedure. The blood does not flow in a jet, but continues to trickle in an oozing stream, apparently from the capillaries rather than from the larger vessels of the part. In these cases, also, there is a great tendency to inordinate ecchymosis from very slight contusion.

In these families of bleeders, it is scarcely necessary to say that it is imperative to be careful to make no surgical wounds, even of the most trivial character, if they can possibly be avoided. Above all, the extraction of teeth must be avoided. It is after this slight operation that the most uncontrollable and fatal hemorrhages have occurred. The hemorrhages, though usually traumatic, may be spontaneous; they then usually proceed from the nose,

bowel, kidney, or subcutaneous connective tissue. In women they assume the character of profuse and uncontrollable menorrhagia. The hemorrhages are accompanied by the symptoms described at page 395, vol. i., as characterizing excessive loss of blood; and after their cessation the patient remains anemic usually for many weeks or months. The quantity of blood lost is often enormous, amounting in some cases to several pounds in the twenty-four hours.

The tendency to bleeding is chiefly from recent wounds or healthy mucous membranes, and sometimes does not occur from diseased surfaces from which it presumably would be likely to happen. Thus a member of one of the three families of bleeders, who have been frequently inmates of University College Hospital, died lately of phthisis, with large cavities in the lungs. A few weeks before his death he had nearly died of hemorrhage after the extraction of a tooth, but he had never suffered from serious hæmoptysis. In another case the patient passed through an attack of typhoid fever without serious hemorrhage. In another a large slough formed in the skin after the application of perchloride of iron, cold, and pressure to arrest hemorrhage from a punctured wound of the leg, yet the slough separated, and the large granulating sore healed without any recurrence of the bleeding.

Formerly it was supposed that females were exempt from hæmophilia. But Wickham Legg, to whom we are indebted for an excellent monograph on this condition, states that this assumption can no longer be maintained, although women are far less disposed to the disease than men; that they present few instances of the more typical forms of the disease; and that it is less fatal in them than in men. Most of the fatal cases in women have occurred by hemorrhage from the genital organs, and Legg quotes a case from Wickham Legg, "where the rupture of the hymen on the marriage night caused the death of the bride from hemorrhage."

A frequent symptom accompanying this diathesis is a painful and sudden swelling of one or more joints either occurring spontaneously, or as the result of some slight injury. The swelling is the result of an effusion of blood and synovia into the synovial membrane. It is usually accompanied by some slight febrile disturbance. It may last only a few days or may endure for months. The joint is often permanently weakened, and relapses are frequent during the cure.

PATHOLOGY.—Little if anything is known with certainty about the nature of this peculiar affection. It has been stated that in some cases the inner coat of the arteries has been found abnormally thin, and degenerative changes have been observed in the endothelium, but the observations are not sufficiently numerous or uniform for any theory to be founded upon them. From the influence exerted by cold in the arrest of the bleeding, it may be reasonably suspected that a want of proper contractility in the arteries may have some influence in causing the bleeding. With regard to the condition of the blood, varying statements have been made: it has been said to be watery, deficient in corpuscles, and uncoagulable. In the cases, however, which have been admitted into University College Hospital, the blood in the earlier stages of the hemorrhage coagulated healthily and was of good color, though after great loss the tint became paler and the coagulum less firm. Accurate analyses of the blood from bleeders are still wanting. It has been suggested as another explanation of the disease that its real cause is an excess of blood, but of this also there is no definite evidence. It would appear then that the only facts of importance that we at present possess to throw light on the cause of hæmophilia are, that it is hereditary; that it is far more frequent in males than in females; and that it is congenital, and may occur in all races and in all countries.

TREATMENT.—In true hæmophilia no remedies appear to exercise the slightest influence over the diathesis. At the same time, it would be wise that the subject of this unfortunate condition should attend to those ordinary rules of health, the neglect of which, by lowering "his condition," might favor the tendency to bleed. Legg especially recommends the use of cold baths of plain, sea, or chalybeate waters, residence in a dry air, and the use of warm clothing. The preparations of iron are usually given in a routine way, but it is doubtful if they have ever been of service in preventing the hæmorrhages, certainly never in arresting them, though they may be of use in removing the anæmic state left after a copious bleeding. Ergot has been given during the bleeding in many cases, but without evident effect.

The *Local Treatment* is that on which most dependence will necessarily be placed. It consists in the use of three means, viz., Pressure, Styptics, and Cold.

Pressure is to be relied on only in one form of hæmophilic bleeding—viz., the continuous hæmorrhage from the socket of a tooth after extraction. In these cases the cavity should be cleared out and carefully plugged from the bottom by means of lint or agaric, the whole retained by means of a piece of oak and a gutta-percha cap to fit over the neighboring teeth, and compressed by a bandage applied under the chin against those in the sound jaw. When the hæmorrhage occurs from the soft parts, pressure must be used with great caution lest sloughing occur; the integuments being extremely liable to give way extensively under very moderate pressure, large subcutaneous extravasations developing at the same time, and thus increasing materially the danger of the case and the local mischief.

Compression of the main artery of the limb is useless and liable to the objection of the development of ecchymoses and subcutaneous hæmorrhages.

Styptics of all kinds have been used as a matter of course, and the perchloride of iron has enjoyed especial favor. I have used and seen it used frequently, and can safely say that I have never seen any permanent benefit from its application, or that of any other styptic, in these cases. Indeed, great evil has often resulted from the inflammation excited by the application of styptics of any kind. The parts become swollen, fall into slough, and as they separate the oozing may recommence from the raw surface, and the same process has to be gone through again.

The **actual Cautery** presents the same inconveniences as ordinary styptics. It may arrest temporarily the bleeding, but inflammation is set up in the parts beyond the limit of the eschar, and this on separating leaves an extended ulcerating surface which bleeds again, and perhaps more freely than before.

The continued application of **Cold** appears to arrest hæmophilic bleeding more effectually than any other means, and this circumstance would lead to the belief that the hæmorrhage is due to want of contractility in the smaller arteries rather than to want of coagulability in the blood. The cold may be applied by means of irrigation of iced water, as has been done successfully by Marshall, or by the application of ice either directly to the part or laid upon a sponge covering it, as has been done in some of the cases of hæmophilia occurring at University College Hospital. Simple water may be used, or a weak antiseptic solution of boracic acid. If the bleeding wound be in the extremities, the limb should be elevated and kept at rest on a splint.

The Surgeon has already been cautioned as to the inexpediency of performing any operation, except under circumstances of the most urgent necessity, on any member of a family of bleeders, or on an individual known to be the subject of hæmophilia. Should an operative procedure become necessary, it should, if possible, be undertaken with Paquelin's thermo-cautery,

if it be desired to make a simple incision; by the galvanic *écraseur*, if it be expedient to remove a part or to perform a small amputation. In the event of the galvanic *écraseur* not being at hand, the *elastic ligature* would be the best substitute.

CHAPTER XLII.

DISEASES OF ARTERIES

ARTERIES are liable to numerous diseases which derive great importance from the effects they produce, both upon the vessels themselves and upon the parts to which they carry the blood. Amongst the most important are the various forms of inflammation or arteritis. The inflammatory affections of arteries are divided first into two classes, viz., those resulting from injury, and those arising from general or local causes not of a traumatic nature. Inflammation of the arteries is divided also into endarteritis, in which it affects primarily or chiefly the internal coat, and periarteritis, in which the process commences in the outer coat or sheath. The term *mesarteritis* has also been suggested for inflammation of the middle coat, but it is of little use, as no true inflammatory affection commences in that part of the vessel. Some forms of arteritis are named from the cause of the disease, as syphilitic or embolic. As in other structures, the inflammatory process may be acute or chronic. In addition to the above diseases, arteries suffer from various degenerative changes, some of which are primary, affecting the original tissues of the vessels, others are secondary, the degeneration taking place chiefly in the products of a chronic inflammatory process. These various processes are still further complicated by secondary effects, such as the formation of aneurism, from the diseased walls of the artery yielding before the pressure of the blood, and thrombosis of the affected vessel followed by its obliteration, and sometimes by embolism and gangrene.

In discussing the diseases of arteries, it will be most convenient to consider first the various forms of inflammation; secondly, the degenerations; and lastly, the remoter effects of these changes.

ARTERITIS.

Acute Arteritis of idiopathic origin, that is to say, arising as an independent affection for which no evident cause can be found, was formerly believed to be a comparatively common affection. It was supposed to affect the inner coat, spreading along the vessel in the direction of the circulation, and from this fact it was spoken of as diffuse or erysipelatous. It is now known, however, that no such affection really exists, and that the error arose partly from assuming that thrombosis is invariably evidence of previous inflammation of the affected vessel, and partly from mistaking for the redness of inflammation the staining of the intima, so often observed as the result of changes in the blood with disintegration of the red corpuscles, occurring either during life in acute forms of blood poisoning such as septicæmia or malignant fevers, or after death as the result of putrefaction.

Traumatic Arteritis—Simple acute traumatic inflammation limited to the part injured and showing no tendency to extension, is familiar to every

Surgeon in connection with contusion, laceration, wound, or ligature of arteries; for in the early period of repair after any of these injuries, inflammatory exudation from the vasa-vasorum forms an essential part of the process. For a description of this condition, the reader is referred to vol. i. chap. xiv.

Arteritis by Extension, from infective inflammation or ulceration of the tissues surrounding the vessel, has already been described as one of the dangers accompanying these processes. In inflammation affecting an artery in this way, the process is the same as in other tissues. The vessels of the outer coat are dilated, inflammatory exudation with migration of corpuscles takes place, and the wandering cells infiltrate the coats of the artery, which become swollen and softened. The process spreads from the outer to the inner coat, the endothelium desquamates, and fibrin is deposited upon the diseased surface. In the smaller arteries complete thrombosis takes place, and the clot extends upwards to the nearest branch beyond the inflamed part of the vessel, and may then undergo the changes already described as occurring in the permanent closure of an artery (vol. i., Wounds of Arteries), and hemorrhage is thus prevented. In arteries above the size of the radial, however, the closure of the vessel is frequently not accomplished before the coats are so far softened as to give way before the pressure of the blood, and thus fatal hemorrhage may result. This is all the more likely to occur when the inflammation and subsequent ulceration affect a limited portion of one side only of the artery, as in those cases in which it is due to the contact of an irritating foreign body, such as a sequestrum. In the larger arteries complete thrombosis occurs much less readily than in smaller vessels or in veins, the rapidity of the flow of the blood being unfavorable to the adhesion of the white corpuscles, which is the first step in thrombosis.

In arteries which have been divided and secured by ligature or otherwise, the extension of unhealthy inflammation from the wound to the exposed end of the vessel, followed by softening of its coats, and disintegration of the contained clot, is the commonest cause of secondary hemorrhage.

Embolie Arteritis.—Moxon has pointed out that a form of acute arteritis, resulting in softening and swelling of the arterial wall, thus leading to the formation of an aneurism or to rupture of the vessel, is in rare cases the result of the lodgement of an embolus. A simple fibrinous embolus lodging in an artery merely obliterates the vessel without causing softening of its coats. In order that inflammatory softening may occur, it is necessary that the embolus should be derived from a part which is the seat of some infective inflammation, and that it should carry with it the unhealthy products of the process. Embolic arteritis is most likely to occur in the somewhat rare affection known as ulcerative or infective endocarditis, but it has also been known to follow embolism during the course of an ordinary case of acute rheumatism. Localized arteritis arising in this way is believed to be the most common, if not the sole cause of spontaneous aneurisms in children, and in the smaller vessels of the extremities in adults. Rushton Parker has recorded a case which well illustrates this form of disease. A boy, aged 14, during an attack of acute rheumatism was suddenly seized with pain in the forearm, followed by swelling of the limb. The general swelling soon subsided, leaving a deeply seated circumscribed tumor, which steadily increased in size for the next four months. On laying this open, a cavity was exposed containing more than a pound of dark clotted blood, and the anterior intercostal artery was found to communicate with it by an opening a quarter of an inch in length. The vessel was successfully ligatured above and below the opening, and the boy recovered. At the time of the operation there was a loud double aortic murmur.

Acute Endarteritis.—Cornil and Ranvier describe under this name an affection of the inner coat, met with chiefly in the aorta, but occasionally also in smaller vessels, especially near wounds. It is characterized, to the naked eye, by prominent patches formed by a swelling of the intima. They are circular or oval in outline, and seldom exceed half an inch in diameter, though both their form and size may be altered by the coalescence of neighboring patches. They are pale pink in color, and semi-transparent or opalescent; in consistence, they are soft and elastic, almost gelatinous. The internal surface has often lost its polish, in consequence of the irregularity of the swelling, but its endothelial covering is usually intact. The middle coat beneath the patch appears usually to be somewhat swollen, and this condition is more marked in the adventitia. Microscopic examination shows that the swelling is due to an accumulation of small cells, either round or slightly irregular in outline, between the fibres of the sub-endothelial connective tissue and the elastic layers of the inner coat. These cells have a distinct nucleus surrounded by a small quantity of protoplasm, and show signs of active growth. Cornil and Ranvier believe they are produced by proliferation of the original cells of the part. The swelling of the external coat is found to be due to the presence of numerous cells of new formation separating the fibres of the connective tissue.

The conditions under which acute endarteritis occur are not clearly determined, but as every intermediate condition between it and the chronic form to be immediately described, is to be met with, sometimes even in the same vessel, it seems to be nothing more than the same process increased in intensity.

Chronic Endarteritis, Arteritis Deformans, Atheroma.—This is by far the most common disease to which arteries are liable; in fact, it is very rare after middle life to find it completely absent in the larger vessels. It occurs in its most marked form in the aorta and the large arteries of the neck, abdomen, the upper parts of the limbs, and the base of the brain. It is less commonly seen in the smaller vessels, in which the muscular coat is more fully developed.

Chronic endarteritis first appears as pale yellowish patches or streaks, smooth, slightly elevated above the surface, and evidently seated in the deeper layers of the inner coat. They are irregular in outline, their long diameter is usually in the line of the vessel's course, but they show a special predilection for the mouths of the branches leaving the main trunk, round which they form annular elevations. Their outline becomes subsequently more irregular by the coalescence of neighboring patches. As the disease advances, the patches become more elevated, often reaching a line or more in thickness. At this stage they are gray, semi-transparent or opalescent, and inelastic, sometimes almost cartilaginous in appearance and consistence. This condition is, however, speedily followed, before the patches have reached more than half an inch in diameter, by a change to an opaque yellow color, the alteration in tint commencing in the central parts. This change is due to fatty degeneration, and is accompanied by some loss of toughness. The further progress may be in one of two directions, the growth may soften and break down, or it may calcify. When softening takes place the patch becomes converted into a pulsatous or cheesy mass, and even sometimes undergoes complete liquefaction into a yellow creamy fluid, which has been mistaken for true pus, and termed an "*atheromatous abscess*." It is this change that led to the term *atheroma* being applied to the disease, the products of the softening of the patch resembling the contents of an *atheromatous* cyst of the skin. The term is now often extended to all stages of chronic endarteritis.

When the process reaches the more advanced stages the middle coat is

affected, first by chronic inflammation, and subsequently by softening. At the same time considerable thickening of the external coat takes place by the formation of dense fibroid tissue which is not prone to fatty degeneration and softening. Up to this stage the fatty patch is covered by the most internal layers of the intima and the endothelium, which are not affected by the chronic inflammatory process, but after complete softening these give way, and the atheromatous fluid is discharged into the circulation, leaving the remains of the patch exposed to the blood-stream. The raw surface thus formed is called "*an atheromatous ulcer*." The debris which enter the circulation are carried on and lodge in the capillaries, but not possessing any irritating properties they give rise to no evil consequences. Although on the formation of an atheromatous ulcer a considerable part of the inner and middle coats are lost, perforation or rupture of the artery rarely takes place, and it is only in exceptional cases that the blood forces its way amongst the coats of the diseased vessel. This is due to the fact that at the margins of the patch, the chronic inflammatory process has led to firm matting together of the coats of the artery. At the same time the thickening and induration of the external coat prevent perforation. It is especially opposite the deeper and more eroded atheromatous patches that this consolidation of the external coat takes place. The change, although described as a chronic inflammation, is strictly conservative in character. The new growth of fibroid tissue is not confined to the external coat, but extends to the sheath of the vessel, and, by soldering it to the contained artery, greatly adds to the strength of the vascular wall.

Although perforation is thus prevented, the new tissue but imperfectly represents the normal structures of the coats of an artery, as it is entirely wanting in elasticity. Consequently it is very apt to yield slowly to the pressure of the blood, and thus lead to the formation of a sacculated aneurism, the mouth of which will correspond to the damaged portion of the wall of the vessel.

Complete softening, with the formation of an atheromatous ulcer, is not by any means a necessary consequence of fatty degeneration of the patches resulting from chronic endarteritis. In many cases the new tissue, after degenerating, remains as a firm, yellow, opaque mass, and may undergo no further change, but most commonly lime salts are deposited in it, and it gradually becomes converted into a hard calcareous plate, over which the superficial layers of the inner coat with the endothelium may remain unbroken. Sometimes, however, these seem to wear away and the calcareous plate comes in direct contact with the blood-stream. This change was formerly described as "*ossification of the arteries*," but it need not be said that no true bone is formed. From the arrangement of the calcareous matter in plates corresponding to the atheromatous patches in which the lime salts have been deposited, this change has also received the name of *laminar calcification*.

Microscopic examination of an atheromatous artery in the early stage of the disease shows that the morbid change commences in the deeper layers of the inner coat by a proliferation of the flattened cells that lie between the laminae of connective tissue of which it is chiefly composed. The new cells are arranged in lines between the laminae. With the proliferation of the cells there is a growth of new laminae of connective tissue closely resembling that of the healthy inner coat, both in appearance and in arrangement. The change is therefore a true overgrowth of the deeper layers of the intima. The relative amount of cells and fibrous intercellular substance varies in different cases, but the chief bulk of the new tissue is always composed of the latter. The cells are small, rounded or slightly flattened, and

contain a nucleus of considerable size, round which it is often difficult to recognize any protoplasm. No vessels penetrate the new tissue and consequently when it reaches a certain stage of development the central parts are but imperfectly nourished, and degeneration commences. The cells become shrivelled and granular, and fatty granules also appear in the intercellular substance. At a later stage calcareous granules may also make their appearance.

Fig. 435.—Atheroma, with abundant cholesterol.

If softening takes place, the fat-granules increase in quantity, and solution of the intercellular substance follows. If complete liquefaction takes place, the atheromatous fluid is found under the microscope to be composed chiefly of fatty debris and oil globules, and very frequently it contains plates of cholesterol (Fig. 435).

The accompanying drawing (Fig. 436) illustrates the structure of an atheromatous patch very well.

The changes in the middle and outer coats require but little notice. The middle coat in the later stages is often invaded by a growth similar in character and structure to that which originally started in the inner coat. In fact, it seems to be an extension of the same growth, the true structures of the middle coat being atrophied from pressure. The outer coat shows a growth of new fibrous tissue containing a number of small round, or elongated cells.

Fig. 436. Atheroma of Aorta. *e*, elastic lamina; *m*, middle coat; *i*, internal coat; *f*, the new growth undergoing fatty degeneration.

Nature and Causes.—The views as to the nature of the disease have undergone various changes, but at the present time it is almost universally regarded as a chronic inflammatory process, characterized by overgrowth of the affected tissue followed by degeneration. Gulliver was long ago inclined to this opinion, and it has been especially insisted on by Virchow, Billroth, and Moxon. That it belongs to the class of morbid processes almost universally spoken of as chronic inflammations, may be said now to be gener-

ally accepted, but the difference between these and acute inflammation is so marked that probably, with the advance of pathological knowledge, a complete separation will be made between them.

The most important cause of chronic endarteritis is mechanical strain. This may be constant, as the result of abnormal resistance in the capillaries or smaller arteries, or intermittent, such as occurs during violent exertion, in which, while the heart is beating forcibly, the resistance to the circulation is increased by the contraction of the muscles. Moxon has brought forward abundant evidence in proof of this theory. He points out that atheroma occurs more constantly and at an earlier period in males than in females, and that when extensive atheroma is met with in women, it will usually be found that they have been engaged in hard manual labor. In men, the most marked examples are met with in those whose occupations have involved violent physical exertion. In wasting diseases, in which the quantity of blood is diminished and the arterial tension reduced, atheroma is seldom met with, and in the pulmonary arteries, in which the pressure is greatly less than in the systemic vessels, chronic endarteritis is rare, being observed only in those cases in which the right heart is hypertrophied in consequence of chronic bronchitis and emphysema, or obstruction at the mitral orifice. The earliest patches of atheroma are moreover situated in the parts exposed to the greatest strain, as in the arch of the aorta, and at the points at which large branches are given off or a trunk bifurcates. It is common also to find the disease more advanced in those situations in which the artery is placed in close proximity to a bone, as in the femoral at the brim of the pelvis. The fact that chronic endarteritis is always more marked in the vessels of the lower limb than in those of the upper may also be explained by the pressure being greater in the most dependent parts while the body is in the erect position.

Among the constitutional affections which predispose most powerfully to the development of atheroma is chronic Bright's disease, with the granular contracted kidney. Gull and Sutton have demonstrated that this disease is associated with a general change in the smaller arteries and capillaries to which they have given the name of *arterio-capillary fibrosis*. It is characterized by a fibroid thickening of the external coat of the smaller arteries. In the diseased kidney, Johnson has described a thickening of the walls of the smaller arteries, which he believes to be due chiefly to the hypertrophy of the muscular coat. The nature of these changes and their extent is still a matter of dispute; but whatever the exact pathological change may be, it is beyond a doubt that it causes considerable obstruction to the circulation, a fact which is made evident by the hypertrophy of the heart that accompanies the disease and the evidence of increased arterial tension as indicated by the sphygmograph. The granular contracted kidney and the general vascular changes associated with it are very commonly the result of *gout*, so much so that this form of Bright's disease is often termed the "*gouty kidney*." Gout is usually the result of an abuse of alcoholic stimulants, and thus habitual alcoholic excess comes indirectly to be an important cause of chronic endarteritis.

The influence of *syphilis* in the causation of atheroma is a more doubtful point. Aitken attaches great importance to it. The effect of syphilis in causing disease of the smaller arteries, and fibroid induration of organs and tissues, has already been pointed out (see *Syphilis*, vol. i.), and it is evident that these changes would tend to obstruct the circulation and thus cause increased arterial tension. Whether it acts more directly as a cause of atheroma is uncertain.

The most important predisposing cause of chronic endarteritis is *old age*.

After a certain period of life the arteries in common with other tissues become impaired in structure. This manifests itself chiefly by a diminution in the normal elasticity of the coats, so that they become less capable of withstanding any strain to which they may be exposed. So frequent, and indeed constant are these transformations of the arterial coats during the decline of life, that they may be considered the natural result of the diminution of the nutrient activity consequent upon advance in years. Gimetta has found that there is a progressive increase in the earthy matters contained in the coats of healthy arteries as the individual advances in life. Thus he ascertained that the ash of the arteries of a newly born child yields 0.86 per cent. of phosphate of lime; the healthy arteries of an adult 1.25; and those of an old man 2.77 of the same salt; whilst the calcified arteries of an aged man contain 4.01. There is no precise period of life at which these changes set in; old age is a relative term, and, so soon as the system has passed its full maturity, in whatever year of life this may happen, there is a tendency for these degenerative changes to take place. The tendency to early degeneration of arteries is frequently hereditary.

Effects of Chronic Endarteritis. As a consequence of the loss of elasticity resulting from the chronic inflammatory and degenerative changes in the coats of the artery, it usually yields more or less before the distending force of the heart. This change is most marked in the aorta and its primary divisions, but is occasionally seen in the femoral and brachial arteries. The dilatation may be regular, or pouch-like projections may form here and there. At the same time the vessel is often somewhat elongated so as to assume a tortuous form. It is in consequence of these changes that the name *arteritis deformans*, was given to this disease by Virchow. The interior of the dilated vessel is rough and irregular in consequence of the projection of the atheromatous patches, when softening has taken place, "atheromatous ulcers" may be scattered here and there over the surface, and in other cases it may be paved with closely set calcareous plates. When the dilatation reaches a certain degree and is limited to a definite area, the condition is described as a fusiform aneurism, the distinction between that and simple dilatation being only one of degree (see Aneurism).

The loss of elasticity in the coats seriously interferes with the circulation through distant parts, as the natural storage of the heart's force in the elastic walls of the larger vessels by which the continuous flow between each systole is maintained, is no longer possible. The circulation in the extremities is therefore usually feeble, and the nutrition of the parts correspondingly imperfect.

Narrowing or Occlusion of the Branches leaving the Atheromatous Trunk is by no means uncommon. As before stated, the orifices of the branches from the main trunk are common seats of the earliest atheromatous patches. The thickening of the intima may take place in a ring round the mouth of the vessel and thus gradually narrow it. The coincident thickening of the outer coat may still further contract the orifice. When complete obliteration occurs the final obstruction probably takes place by the formation of a thrombus in the diseased artery immediately above the narrowed orifice. Complete obliteration is most common in those cases in which the dilatation of the main trunk has reached such a degree as to merit the name of a fusiform aneurism. In a case in University College Hospital a few years ago, in which the left carotid was tied for aneurism of the innominate artery and the arch of the aorta with an immediately fatal result, it was found that the right subclavian was obliterated where it left the dilated innominate, the right carotid was permeable, but pressed on by the aneurism, and the aortic opening of the left

subclavian was completely closed, thus the artery which was tied was the only vessel carrying blood to the brain.

Narrowing of the coronary arteries by an atheromatous ring at their orifices is a common cause of fatty heart.

Thrombosis is an occasional consequence of atheroma. So long as the patch is covered by an unbroken layer of the inner coat with its endothelial covering, there is no tendency for coagulation to take place upon it. When, however, the patch has softened and discharged into the circulation, leaving an "atheromatous ulcer," or when the thin covering over a calcareous plate has been worn away, the diseased structures come into direct contact with the blood. If the surface is tolerably smooth, the rush of blood past the diseased patch is so rapid that adhesion of the corpuscles is barely possible and consequently no thrombosis results; but in pouch-like dilatations it readily takes place. In the same way it may occur in a very dilated vessel if the heart's action is unusually feeble. A clot thus formed may gradually increase in size till it fills the whole vessel, but more commonly after reaching a certain bulk it is washed away and carried on as an *embolus* to some distant part. If it be of sufficient size to obstruct a main artery of one of the limbs at its bifurcation, gangrene will frequently result. Smaller fragments lodging in the extremities usually produce no important effects, the anastomosing circulation being sufficient to take the place of the obstructed vessel. If lodging in one of the solid viscera, it gives rise to a hemorrhagic infarct (see vol. i. p. 904), but does not as a rule cause any serious consequences.

Syphilitic Endarteritis has already been described (vol. i. p. 1048).

Arteritis Obliterans or *Obliterative Arteritis* (Friedländer). *Endarteritis Proliferans* or *Hyperplastic Endarteritis* (V. Winiwarter).—Under these names have been described certain rare cases in which obliteration of arteries takes place as the result of inflammatory changes in their coats, not evidently dependent on syphilis, embolism, or injury. The disease runs a chronic course, and may cause spontaneous gangrene of the parts supplied by the affected vessel. The symptoms will perhaps be best illustrated by quoting a typical case lately recorded by Pearce Gould. The patient was a brickmaker, aged 19. In May, 1883, the fingers of his right hand became congested and sometimes dead white, with much sickening pain. After a few weeks' rest he improved, but soon relapsed on returning to work. After some months the pain extended into the forearm, and completely incapacitated him from working. He came under Gould's observation in October, 1883. At that time the right forearm and hand were cold and somewhat wasted, and he suffered much pain, especially at night. The brachial artery was harder than natural, and pulsated more feebly than that on the opposite side. The radial could be felt as a solid cord. There was dry gangrene of the tips of three fingers. No constitutional affection was found to account for the condition. Two weeks afterwards the pain increased till it became agonizing, requiring hypodermic injections of morphia for its relief. At this time there was slight elevation of temperature. The brachial artery then became converted into a pulseless cord to within one inch of the *teres major*. Soon after, the subclavian artery was found to be prominent. In December the pain gradually subsided, and one month after he was apparently well. The brachial artery remained a solid cord, and the first joint of the thumb and of the index finger separated after becoming mummified (*vide Trans. Clin. Soc.* 1884). A somewhat similar case occurring in a female, aged 35, is recorded by W. B. Hadden in the same volume. The pathology and causes of this rare affection are still uncertain. It commonly occurs about middle life, Gould's case being the youngest recorded.

The disease described by V. Winiwarter under the name of *endarteritis*

proliferans is probably of the same nature. He states that it occurs in persons apparently healthy in other respects, and gives rise to spontaneous gangrene usually of the foot. In one case in which the vessels were examined after amputation of the limb the obliteration was found to be the result of a great proliferation of the endothelium, with narrowing of the lumen of the vessel, the final obliteration being brought about by thrombosis. New vessels were found penetrating from the outer coat into the proliferating endothelium, which with the thrombus was found in the older parts to be undergoing changes similar to those already described as occurring in closure of an artery after ligation. Billroth states that the disease is preceded by feebleness of circulation, and obscure pain, often lasting for months or years. There is no definite treatment for these cases.

Periarteritis. By periarteritis is meant an inflammation commencing in the outer coat or sheath of the artery. If we exclude arteritis by extension from surrounding tissues and traumatic arteritis, periarteritis is a rare disease. Charcot and Bouchard have described such an affection in the vessels of the brain, commencing as an accumulation of small round cells in the perivascular sheaths; these penetrate the coats from without and lead to softening, frequently followed by the formation of minute aneurisms and final rupture. It is a senile disease, and according to Charcot a common cause of apoplexy.

An affection of the arteries of an uncertain nature not causing obliteration has been observed, which, from its giving rise to acute pain and tenderness with some swelling in the line of the vessel, must be supposed to be inflammatory. A case of this kind has been recorded by J. H. Morgan, in the *Transactions of the Clinical Society for 1881*. The patient, a man aged 46, was attacked with severe pain in the line of the right femoral artery; the vessel was acutely tender, but there was no redness of the skin covering it. The condition was at first limited to a few inches of the artery near the groin, but gradually extended to the popliteal space and leg. Slight oedema and some swelling of the lymphatic glands became apparent when the disease reached the leg. The vessel pulsed forcibly and there was no thrombosis. He had some years previously suffered from a similar affection of the opposite leg, and, while still under observation, the right brachial and carotid were successively affected. Altogether the second attack lasted over five months. It was not apparently due to syphilis, gout, or rheumatism. From the absence of thrombosis, it would seem probable that the disease was a periarteritis.

PRIMARY DEGENERATIONS OF ARTERIES.

Fatty Degeneration.—Fatty degeneration, except as a part of chronic endarteritis, is not a particularly frequent or important change in arteries. In the aorta, even in young subjects, yellow patches of small size and irregular form, and very slightly if at all elevated above the normal surface of the intima, are not uncommon. If one of these be peeled off and examined microscopically it will be found to present stellate patches of fat-granules in the most superficial layers of the intima, immediately beneath the endothelium. These are the result of fatty degeneration of the branched cells that are normally present in this part. The affection seems of no importance, and its cause is not known.

In later life, fatty degeneration affecting the intima more deeply is sometimes met with unaccompanied by any of the signs of atheroma. The degeneration may extend to the endothelium, which then disintegrates and is cast off, leaving a rough surface exposed. This condition has been de-

scribed as *fatty erosion*. It is most common in the arch of the aorta. Through such a surface the blood may force its way into the middle coat, and thus give rise to the condition to be subsequently described as "*dissecting aneurism*."

Fatty granules are not uncommonly found in old age in the external coats of the smaller arteries, but they are of no pathological importance.

Calcification or Calcareous Degeneration.—We have already seen that the calcareous plates so common in the aorta and its primary branches are the result of the calcification of the products of chronic endarteritis. In the smaller arteries, principally in those of the third and fourth magnitudes, as the popliteal, the tibials, the brachial, radial, and ulnar, primary calcification is commonly met with. It commences by the deposit of lime salts, in a granular form, arranged in lines running transversely to the axis of the vessel; these lines gradually increase in breadth until they coalesce laterally, the intervening spaces being filled up and the vessel converted into a rigid tube. In the early stages while the calcareous matter is arranged so as to form lines round the vessel, the condition is termed *annular calcification* (Fig. 437). When these lines have coalesced, it is often called *tubular calcification* (Fig. 438).

When this process has reached its highest stage, if the artery be removed from the body and drawn through the fingers, a small rigid tube, composed of the calcified middle coat still lined by the inner coat, can be squeezed out, leaving the external coat apparently healthy. In fact, the toughness of the

Fig. 437.—Annular Calcification.

Fig. 438.—Tubular Calcification.

external coat is so little impaired that such vessels can be tied, and even twisted, almost as safely as a healthy artery. Annular and tubular calcification are almost invariably associated with chronic endarteritis, and its secondary degenerations in the larger vessels, and in the intermediate arteries, such as the axillary or popliteal, and sometimes even as low as the tibials, both conditions are observed side by side.

The existence of this degenerative change is usually recognized without difficulty during life in any artery that can be examined with the finger. The vessel feels hard and less compressible than natural. Its longitudinal

elasticity is lessened, so that it is thrown into a wavy line when relaxed longitudinally by flexion of the limb.

The morbid condition consists essentially of a deposit of lime salts in the muscular fibre-cells of the middle coat. We thus only meet with it in those vessels in which the muscular tissue is well developed. In the larger arteries the muscular cells are so scanty and so far concealed by the elastic tissue that if this change does occur in them it is difficult to recognize. The inner coat in the larger vessels usually shows the ordinary signs of chronic endarteritis. In the smaller it may at first be healthy, but later on calcareous plates may form in it. It has been pointed out by Bizot that the symmetry of the arrangement of these morbid appearances in the corresponding vessels on opposite sides of the body is remarkably great, the arteries of one limb being often the exact counterpart in this respect to those of the other.

The causes of calcification of the muscular fibre-cells of the middle coat are unknown beyond that it is always a senile change.

The effects of annular calcification are to render the vessel a rigid tube no longer capable of regulating the flow of blood to the parts it supplies. At the same time its calibre is always diminished, and the nutrition of the parts beyond is seriously impaired. Thus in the limbs we have all the signs of defective circulation, coldness of the feet, cramps and spasms of the muscles; whilst, in organs, softening of tissue, fatty degeneration, and other evidences of want of a proper supply of blood are observed. Spontaneous aneurisms rarely result from this change, the coats of the artery being more resisting than natural; moreover, primary calcification is met with in the vessels below the axilla and knee, and spontaneous aneurisms beyond those points are amongst the curiosities of surgery. Thrombosis is occasionally met with, but is not common, as the endothelial lining is affected only in extreme cases and late in the disease. The lodgement of a small fibrinous embolus carried from atheromatous arteries above is an occasional occurrence, and is very likely to cause gangrene even when only one vessel is blocked, as the collateral arteries are no longer capable of enlarging to carry on the circulation. Occlusion of the calcified arteries by thrombosis or embolism is the common cause of the dry form of senile gangrene. The moist form arises from inflammation taking place in tissues, the vitality of which has been greatly lowered, in consequence of the diminished supply of blood which finds its way through the narrowed vessels.

Ossification of Arteries.—The formation of true bone in the coats of an artery is an extremely rare occurrence. I am acquainted with only one authentic case of this change. The specimen was exhibited at the Pathological Society of London, by H. G. Howse, in 1877. The patient was a man aged 36, who was run over by a cart, the wheel passing over his shoulder. The axillary artery was ruptured, and death occurred as a result of the accident about a month afterwards. A small plate of cancellous bone was found in the injured vessel, apparently developed in the middle and outer coats. Its greatest thickness was about a quarter of an inch.

EFFECTS OF DISEASES OF THE ARTERIES.—The various effects of diseases of the arteries have already been mentioned with the affections to which they are due, but it may lead to a clearer comprehension of the subject if they are again referred to, as the same effect may result from more than one cause. The most important effects of arterial disease are Ulceration of the Coats of the Artery; Spontaneous Rupture; Contraction or Occlusion of the Vessel, and, lastly, Distention into some of the various forms of Aneurism.

Ulceration of Arteries.—Loss of substance in the inner coat results from superficial fatty degeneration (p. 116) and from softening of an atheromatous

patch (p. 110). Neither of these processes is a true ulceration. Genuine ulceration of the inner coat is in reality scarcely ever met with. When true ulceration of an artery takes place, it is the result of causes acting from without, attacking first the external coat, as in the case of a sloughing sore opening a main artery, or the pressure of a sequestrum in the popliteal space against the vessel.

Spontaneous Rupture of an artery is rare, and never happens without previous disease of its coats. Experiments made by Peacock, which I have repeated, and the accuracy of which I can fully confirm, prove that a healthy artery will sustain a very great pressure from water injected into it, without its walls giving way. But, if these have been softened or weakened by disease, they may be unable to resist even the ordinary impulse of the blood; and if this be driven on by any unusually forcible action of the heart, as under the influence of sudden violent strain or exertion, they may give way. This occurrence would be much more frequent than it is in atheromatous and calcareous patches, were it not for the inflammatory consolidation of the external coat of the vessel supplying that resistance which has been lost by the softening or destruction of the internal and middle tunics. Hence this rupture is most frequent in those vessels the outer coat of which is thinnest, and in which, consequently, it can least supply the place of the others, as in the arteries of the brain and in the intrapericardial portion of the aorta. The liability to rupture of a diseased artery by the distensile force of the blood impelled into it, is greatly increased by the existence of an obstacle to the free flow of the blood out of its terminal branches in consequence of a congested, infiltrated, or chronically thickened state of the organ or part supplied by it.

Contraction and Occlusion of arteries are by no means rare sequences of lesions of these vessels. Narrowing of an artery may take place in various ways; the orifice of a branch leaving an atheromatous trunk is often narrowed by the formation of a ring-shaped thickening of the inner coat (p. 114), and the calibre is diminished in calcification of the middle coat (p. 117), syphilitic arteritis (vol. i. p. 1048), and endarteritis proliferans (p. 115). Causes acting from without, as pressure, or contraction of chronic inflammatory or cicatricial tissue in the immediate neighborhood of the artery, lead to a narrowing of its lumen. In this way the axillary, the iliac, and even the aorta, have been occluded. Tiedemann records from various sources no fewer than eight cases in which the abdominal aorta was completely closed, in all of which so full and efficient a collateral circulation had been set up, that the vitality of the lower part of the body was perfectly maintained, and in most the morbid state was not suspected during life. Besides these cases he states that there are on record twelve instances of great narrowing of the aorta, at that point where the ductus arteriosus is implanted into it in fetal life. These would appear in some way connected with the closure of the duct; as in every case the indentation was greatest on the convex part of the aorta, which had been drawn in towards the mouth of the duct.

The final obliteration of a diseased artery is most commonly the result of thrombosis. Thrombosis takes place in arteries under much the same conditions as in the veins. Whenever the normal endothelial lining of the vessel is lost or its "physiological integrity" impaired by degenerative changes, the blood tends to coagulate upon the diseased surface. The rapidity of the arterial flow, by preventing the adhesion of the white corpuscles, counteracts this tendency to a certain extent, but when the blood-stream becomes slackened either by great dilatation of a large trunk, or by narrowing of the orifice of a branch, or feebleness of the heart's action, a deposit of fibrin very

readily takes place. An artery of the second or third magnitude may thus be obliterated. When a thrombus has formed in a branch it may extend by fresh deposit into the main trunk and form a mass of fibrin projecting into its lumen (Fig. 439). Thrombosis of the diseased artery is probably in a considerable number of cases the final determining cause of dry gangrene in old people.

Fig. 439.—Thrombosis of two of the chief branches of the abdominal Aorta: projection of the thrombus into the main trunk.

Fig. 440.—Embolism of the Axillary Artery with Thrombosis of the Brachial for some distance below the Embolus. 1. Subclavian. 2. Axillary Artery. 3. Subscapular and Post-cervical Arteries. 4. Brachial.

Complete obliteration of an artery is in many cases the result of embolism. The embolus is usually composed of a mass of fibrin which has been deposited on some diseased part of the larger vessels, and subsequently washed away by the blood-stream and lodged in some part at which the trunk suddenly

narrows when bifurcating or giving off a large trunk. The source of the embolism may be the vegetations formed upon the valves of the heart in acute rheumatism or ulcerative endocarditis, the fibrin deposited in a pouch of a dilated aorta, or on a projecting calcareous plate, or a fragment of a clot projecting into the main trunk from a thrombosed branch, as in Fig. 439. The effects produced vary with the nature of the embolus and its size. When derived from the vegetations on the valves in ulcerative endocarditis it may give rise to inflammation and softening of the coat of the artery at the point at which it lodges (see Embolic Arteritis, p. 109), more commonly it leads merely to obliteration of the artery by the ordinary processes already described. If it lodge in a small artery in a part in which the anastomosing circulation is free, it produces no effect beyond the permanent closure of the vessel; if it lodges in a terminal artery, as in one of the abdominal viscera, it gives rise to the formation of a hemorrhagic infarct (vol. i. p. 904) followed by the subsequent degeneration, and shrinking of the affected area. These old infarcts, forming wedged-shaped buff-colored patches of considerable toughness, are commonly met with in the spleen and kidneys in cases of advanced atheroma or fusiform aneurism of the aorta. When the embolus is large and lodges in a main trunk, as in the popliteal at its bifurcation, or in the axillary, spontaneous gangrene may result. This is the common source of gangrene in young people, and is probably the immediate cause of a certain proportion of cases of senile gangrene, the embolus in the latter case being derived from the diseased surface of an atheromatous aorta. The case from which the accompanying drawing (Fig. 440) was taken was that of a woman 56 years of age, admitted for spontaneous gangrene of the left arm; the embolus lodged in the axillary artery had caused gangrene of the limb. The figure illustrates also the thrombosis of the vessel below the part at which the embolus has lodged, which frequently aids in the production of gangrene.

Gradual narrowing of an artery, ending perhaps in complete obliteration, causes few or no symptoms when the area affected is limited in extent and the collateral circulation is sufficiently active to keep up the supply of blood to the parts beyond the obstruction. The gradual narrowing of a considerable extent of the main vessels of the limb, such as is seen frequently from calcareous degeneration of the tibial arteries, gives rise to more or less definite effects, such as cold feet, cramps, numbness, and weakness of the legs. Such symptoms are often the premonitory signs of gangrene (see vol. i. p. 248), and are an indication that care must be taken to keep the parts warm by appropriate clothing and to avoid any injury. The symptoms of embolism of a large trunk have been described already (vol. i. p. 850).

CHAPTER XLIII.

ANEURISM.

By **Aneurism** is meant a tumor, resulting from dilatation of the whole or a portion of the coats of an artery caused by the pressure of the contained blood, and communicating with the interior of the vessel.

Traumatic aneurisms have been already described vol. i. p. 446. Spontaneous aneurisms, arising from disease of the coats of the artery, are alone considered in the present chapter.

CAUSES.—The causes of aneurism are divisible into those that predispose to, and those that excite the disease. Aneurism is **Predisposed** to by any affection of the arterial coats that lessens the elastic resiliency of the vessel, and at the same time weakens its resisting power. When an artery has undergone any of the changes described in the last chapter by which the natural elasticity of the walls is diminished, it becomes less able to contract on its contents, and to recover during the diastole from the distention occurring during the systolic impulse, and thus either complete or partial dilatation of the cavity takes place. I believe that this loss of elasticity and of power of contracting on its contents, which eventually results in the dilatation of the vessel, never occurs except as the result of previous disease of the coats. In the very numerous specimens of dilated arteries that I have examined, I have never found one that has not undergone fatty degeneration, or atheromatous softening. Calcification prevents rather than favors dilatation of the artery, by hardening the coats and converting them into rigid inelastic tubes; but atheroma softens them, and causes yielding of that portion of the vessel affected by it. I have frequently observed that the whole of an artery might be healthy except at one part, where there was an atheromatous patch, and where the vessel was dilated; or that the whole of its coats might be calcified except at one spot, where softening had taken place, and where consequently they had yielded under the outward pressure of the contained blood.

As aneurism, therefore, may be looked upon as one of the sequences of atheroma, the predisposing causes of the one condition must necessarily be the same as those of the other. Hence we find that age, gout, and syphilis influence the occurrence of the aneurismal disease by laying its foundation in the development of atheroma.

Age exercises a powerfully predisposing influence on the occurrence of aneurism. It is during the middle period of life, about the ages of thirty and forty, that aneurisms are most frequently met with; at these ages, indeed, when the arteries have already commenced to lose their elasticity, in consequence of degenerative changes, whilst, at the same time, the heart has not lost any of its impulsive force, or the general muscular system its contractile vigor; and when the enfeebled and inelastic vessels, becoming exposed to powerful causes of distention, may readily give way or be expanded at some one weakened point. This disease is excessively rare before puberty, yet is occasionally met with at early periods of life: thus *Some* mentions a case of popliteal aneurism in a boy of seven, *Hodgson* had a preparation of a carotid aneurism in a girl of ten, and *Schmidt* a case of

spontaneous aneurism of the radial artery in an infant eight weeks old. R. W. Parker, in a most valuable paper on aneurisms in young subjects read before the Medico-Chirurgical Society in 1883, states, that after a careful search in medical literature, he has found only fifteen cases of spontaneous aneurism recorded as occurring under the age of twenty, including a case of his own of inguinal aneurism in a boy aged twelve years and eight months. In eight of the fifteen cases there was disease of the valves of the heart, in five the state of the heart was not recorded, and in two only was it healthy.

A forcible, irregular, and occasionally greatly increased action of the heart is the immediate cause of the over-distention and dilatation of the vessels, and thus of the production of aneurism. Hence we find that this disease is especially apt to be induced in those individuals in whom the muscular system is called upon to make sudden, violent, and intermittent exertions; as, for instance, in men who habitually lead somewhat sedentary lives, but occasionally and suddenly change their habits, and indulge in sports, such as hunting, rowing, or a long day's shooting, which they might without risk have practised in early life, but which cannot be taken up with impunity at an age when the arteries, having become weakened, are unable to bear the same strain upon their coats as heretofore. I agree with Porter, in thinking that continuous, steady, laborious employments do not predispose to aneurism, as this disease is seldom met with amongst those of the working class who labor hard and uninterruptedly; but it occurs rather in those who, after long periods of comparative inaction, are occasionally and suddenly called upon to make very violent muscular efforts, disproportioned to their strength, or, at all events, to their previous habits. It is in this way that soldiers, sailors, and members of the wealthier classes in society, are rendered peculiarly liable to aneurism. As violent muscular strain and exertion predispose to this disease, we should necessarily expect to meet with it more frequently among men than in women; and accordingly Crisp finds that, of 551 cases of aneurism of all kinds, more than seven-eighths occurred in men. It is important, however, to observe that different kinds of aneurism occur with varying degrees of frequency in the sexes; thus, this affection is met with in the carotid artery about as often in women as in men, whilst the other external aneurisms occur in the proportion of thirteen cases in males to every one among females. It is remarkable, however, that in the dissecting aneurism the proportions are reversed; for every one case in men, two occur in women.

Climate exercises an important influence on the occurrence of aneurism, which is far more frequent in cold than in hot countries. It is not, however, the geographical position or the meteorological state of a country that exercises any direct influence over the occurrence of this disease. It is in reality the habits of the people that dispose to it, and that regulate its prevalence; and it is in the more energetic nature and the more active physical habits of the northern nations that we must look for an explanation of its greater prevalence amongst them, than in the more indolent inhabitants of the South. If we may judge of the prevalence of aneurism in a country by the number of published reports of cases, I should say that it is of more common occurrence in Great Britain and Ireland than elsewhere; indeed, Roux states that it is less frequent in France than in England. In America, it is also of frequent occurrence; but in the East Indies it is comparatively rare.

Cachexy induced by any cause, such as syphilis, chronic gout, or rheumatism, the abuse of mercury, etc., has a tendency to occasion disease of the coats of the arteries, and thus to predispose to aneurism. But, though mercury and syphilis are commonly said to tend specially to the production of this disease, I am not aware that we are in possession of any definite facts

that would warrant us in coming to this conclusion; though it is probable that the cachexy thus induced may dispose to it as much as any other cause. It is remarkable that phthisis is antagonistic to aneurism; though probably this may arise from the facts that the heart's action is feeble in that disease, and that violent muscular exertion is seldom undertaken by those laboring under it.

Any obstacle to the free flow of blood through an organ or the capillaries of a part, exercises an important influence in disposing to aneurism, as it throws an increase of pressure on the interior of the artery. Chevers believes that obstruction in the abdominal organs frequently occasions aneurisms of the abdominal arteries. Spontaneous aneurisms of the smaller arteries, as the radial, ulnar, or tibials, are believed in the great majority of cases to be due to the impaction of an embolus washed on from a diseased heart; but in these cases the obstruction to the flow of blood plays but a secondary part in the process, the most important element being the softening of the coats of the vessel consequent upon the irritating nature of the material of which the embolus is composed. There is no reason to believe that a simple embolus ever causes aneurism (see p. 109).

The only **Exciting or Direct Occasioning Causes** of aneurism are blows, violent strains, and wounds of an artery. When an atheromatous artery is concussed by a *blow*, the lining membrane covering the softened patch may be ruptured, the atheroma being poured out into the interior of the vessel; and the external coat, with perhaps a portion of the middle adherent to it, becoming thus exposed to the pressure of the contained blood before it has been fully consolidated by chronic inflammation and the formation of new fibroid tissue, the foundation of an aneurism may readily be laid. In very forcible muscular efforts, it is easy to understand how an already weakened portion of the vessel may become dilated by the increased pressure that is thrown upon its interior; occasionally even the vessel may be completely torn across by a violent strain. *Wounds* implicating arteries are common causes of those various forms of aneurism that have already been discussed in considering *Injuries of Arteries* (vol. i. p. 446).

CLASSIFICATION—Aneurism may be classified as follows:

1. **FUSIFORM**.—True.

2. **SACCU LATED**.— (a. True. (c. Circumscribed.
(b. False. (d. Diffused.

3. **DISECTING**.

1. **Fusiform or Tubular Aneurism**.—This is a preternatural dilatation of an artery, all the coats of which are equally expanded through the whole circumference of the vessel. It occurs most frequently in the aorta, and may, though rarely, be met with elsewhere. The fusiform aneurism is not a mere dilatation of the vessel, for there are elongation, thickening, and degeneration of its walls as well. The elongation of the artery in the fusiform aneurism is as marked as its dilatation, and is always very considerable. Thus the arch of the aorta may be increased in length by some inches, with a considerable space between the origins of the innominate, the carotid, and the subclavian, at the same time that its walls are greatly thickened, nodulated, and rugged. Sometimes several tubular or fusiform aneurisms are met with in the same vessel, with healthy portions of the artery between them. From these dilatations, sacculated aneurisms not uncommonly spring.

On examining the structure of a fusiform aneurism, it will be found that it is composed of an expansion and outgrowth of the coats of the artery. The thickness of the wall is maintained by growth from the inner and outer coats, the middle coat being stretched and atrophied in proportion to the

around the aneurism. The inner coat presents the changes already described as resulting from endarteritis; it is stiff, rugged, and tuberculated from the deposition of atheromatous patches, and frequently calcareous plates are scattered over its surface. The outer coat is thickened and composed of fibrous tissue. Microscopic examination shows that the middle coat is wasted in proportion to the degree of dilatation. If the aneurism is of any considerable size, gaps are found here and there in which the middle coat is wanting, the diseased inner coat coming into direct contact with the thickened outer coat. No coagula are found in the dilatation, but a few filamentous pieces of fibrin are occasionally seen to be attached to the inner wall. The arteries that are usually the seats of fusiform aneurism are the arch of the aorta (Fig. 441), the iliacs, the femorals, and occasionally the axillaries. This peculiar form of aneurism occurs most generally in vessels in which the yellow elastic coat is largely developed, and hence is rarely met with in arteries smaller than the femoral; it occurs, however, in the basilar artery of the brain.

The fusiform dilatation, especially when situated in the arch of the aorta, attains a very considerable magnitude and may consequently exercise very serious pressure on contiguous parts thus producing great distress and danger of life. It is usually extremely slow, increasing very slowly, and being compatible with existence for many years, but it usually destroys the patient at last, and may occasion death in several ways. Thus, if it be situated in the aorta death may take place from rupture. This may be caused by the distention of the inelastic aorta to fill the coronary arteries during the diastole of the heart, or from imperfect supply of blood to the brain. Then, again, death may result from pressure on important parts such as the bronchi or oesophagus. When, however, a tubular aneurism of the arch of the aorta occupies the intrapericardial portion of the vessel, it not unfrequently happens that, owing to the absence of a sheath in this situation, the artery may rupture. It most commonly happens that a fusiform aneurism remains quiescent, being a source of discomfort, but not of danger, until the sacculated form of the disease springs from its side; and this, being the more formidable affection, may destroy life in some cases before it is perceived.

Sacculated Aneurism.—By the sacculated aneurism is meant a tumor springing from the side of an artery or of a tubular aneurism, with the interior of which it communicates by a narrow aperture, called the mouth of the aneurism (Fig. 442). It is generally divided into the *True* and *False* varieties.

True Sacculated Aneurism.—By this is meant a partial dilatation of all the coats of the vessel. Its existence has been denied; thus Scarpa doubts the occurrence of such a disease, and Bizard seems disposed to coincide with him. With these eminent pathologists, however, I cannot agree; and though I am willing to admit that many of the so-called "true" aneurisms are not such really, yet I cannot doubt, from repeated observation, that Hodgson is

Fig. 441.—Large Fusiform Aneurism of Ascending Aorta bursting into Pericardium.

right in saying that in their early stages sacculated aneurisms are not unfrequently of the true kind. Thus, we occasionally find, as Peacock has pointed out, small digital pouches springing from the walls of some of the larger arteries, through the whole of which the external, middle, and internal coats can be demonstrated by maceration to exist; and in those aneurisms which are formed by the dilatation of a comparatively large portion of the arterial wall, it not unfrequently happens that the tumor remains of the true kind

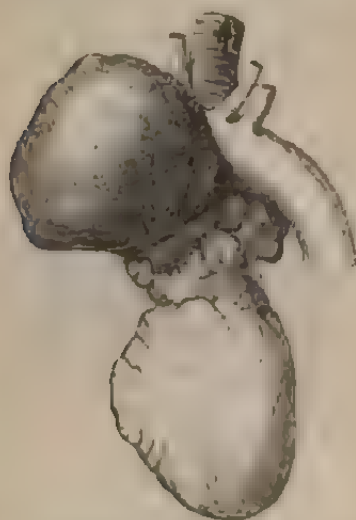

Fig. 442. Sacculated Aneurism of Ascending Aorta. Death by Pressure.

Fig. 443. — Upper part of Descending Aorta half open, showing the mouth of the sac of an Aneurism. The inner coat round the opening is irregular from patches of atheroma and masses of fibrin.

for some time, as I have ascertained by careful dissection. But after an aneurism has attained a certain size, its coats become so fused together, and so closely incorporated with the neighboring tissues, that their precise structure cannot be made out. Indeed, for a sacculated aneurism to be of the *true* kind, I believe that two conditions are necessary: 1, that the tumor itself be small; and, 2, that the mouth of the sac be of tolerably large dimensions. Porter says that he has never met with a *true* aneurism larger than a small orange; and, certainly none of those that I have seen, provided they were of the sacculated kind, have exceeded this size. In true sacculated aneurisms, also, it is necessary that the mouth of the sack, or that portion of it which communicates with the interior of the artery, should be of good size, and not bear too great a disproportion to the wall of the tumor. I cannot conceive a large sac with a small mouth to be a true aneurism. But in all cases of true aneurism, however small they may be, the size of the sac greatly exceeds that of its mouth. It is therefore clear that there must have been not only expansion, but a degree of hypertrophy and overgrowth of the wall of the vessel, just as in the tubular aneurism, otherwise the sac would be thinned in the exact proportion of its expansion. This overgrowth takes place chiefly from the outer coat, and, in a less degree, from the inner and not at all from the middle. When the sac is very small the expanded middle coat can be traced throughout it; when somewhat larger, patches of the middle coat can be recognized with wide gaps between them, but when it reaches any considerable size the greater part is composed of dense fibroid tissue in

which none of the proper structure of the middle coat, and in most cases of the inner also can be demonstrated.

False Sacculated Aneurism is that variety of the disease in which the internal, or the internal and middle, coats have been ruptured, and are consequently deficient. This is by far the most frequent form of sacculated aneurism, and is that which is met with of so great a size. In by far the majority of cases, the internal coat, and the innermost layers of the middle coat, have been destroyed by atheromatous degeneration, leaving an erosion or depression in the interior of the artery, with weakness of the corresponding portion of its wall, which becomes expanded by the outward pressure of the blood. In these cases the sac is formed principally by the outer coat, in which some remains of the middle may still be recognized. That the sac is formed by inflammatory new growth in the external coat and not merely by expansion, is evident by its being thicker than the corresponding coat of a healthy artery. The thickness of the sac is increased when it reaches any considerable size also by adhesion of neighboring parts to it, which become fused into its structure as a consequence of the chronic inflammatory process set up round the aneurism from the pressure it exerts on the surrounding structures. The formation of an aneurism by the hernial protrusion of the internal and middle coats through an ulcerated aperture in the external coat has been described; but, though there is a preparation in the Museum of the College of Surgeons, that is supposed to illustrate this fact, I doubt the existence of such a form of the disease, and after careful examination think that the preparation in question represents rather an artificial dissection than a true rupture of this dense and resisting structure.

A false aneurism may always be readily distinguished from a true one, by the greater magnitude that it attains, by the size of the sac being out of all proportion to that of its mouth, and, on a section of this being made, by the middle coat being seen to terminate abruptly in a thick and dense ring, immediately around the mouth and neck of the sac. A false aneurism may either be so from the very first, the internal and middle coats having been destroyed by softening and erosion, and the external expanded and hypertrophied into a sac; or it may originally have been a true aneurism, and have been converted into the false variety of the disease by the giving way or atrophy of some of its coats.

Surgeons generally recognize two varieties of false aneurism—the *circumscribed* and the *diffused*. By the *Circumscribed False Aneurism* is meant that form of the disease in which the blood is still contained within a sac, formed by at least one of the arterial coats, however expanded and altered in its structure this may be. The term *Diffused False Aneurism* includes two distinct varieties of the disease. In one case there is rupture of the sac, with general and widely spread extravasation of blood into the areolar tissue of the limb or part. In the other case it happens that the sac formed by the dilatation and hypertrophy of the outer coat of the artery is ruptured, and the blood, although effused beyond this, is still confined in a sac of condensed areolar tissue, formed by that of the structures into which the blood has been effused, matted together with coagulum and inflammatory exudation.

3. Dissecting Aneurism is a remarkable form of the disease, originally described by Shekelton, in which the sac is situated in the wall of the artery between its coats. It originates in consequence of the internal coat of the vessel becoming eroded, and giving way before any of that adhesion and matting together of the tissues around the patch has taken place, which prevents the blood from being forced between the different tunics of the artery. The rupture, although originating in the internal coat, always extends

between the layers of the middle one, splitting this up into two laminae, and in some cases it separates also the middle from the external tunic of the vessel. On examining the artery in a case of dissecting aneurism, its coats will always be found to be easily separable from one another, and to be very lacerable, often appearing soft and scalden as if macerated. For the production of this disease, indeed, two conditions are necessary: 1. That there be atheromatous disease of the artery, destroying a portion of the internal and of the innermost layers of the middle coat; and, 2. That there be also a general softening of the tissue of the middle coat, with want of cohesion between the different tunics of the artery; this, indeed, may be considered as the essential condition disposing to the formation of a dissecting aneurism, and causing the disease to assume this rather than the sacculated form.

The rupture constituting dissecting aneurism always takes place longitudinally along the middle coat, and may often extend to a very considerable distance. Thus it may reach from the arch of the aorta to the iliaes, or from the same part to the bifurcation of the carotids. The disease occurs, however, only in the aorta and its principal branches—in those arteries, indeed, in which yellow elastic tissue is abundant in the middle coat.

Classes.—Dissecting aneurisms arrange themselves into three distinct classes: 1. In one class, the blood, after having passed for a distance of several inches, or even more, through the substance of the middle coat, bursts through the external coat, and becomes effused into the areolar tissue

outside the vessel and around the seat of rupture, or into the neighboring cavities (Fig. 444.). In these cases, which constitute the most common variety of the disease, death usually occurs rapidly, the patient feeling intense pain along the line of rupture, and falling into a state of syncope. 2. The external coat may resist the impulse of the blood, which consequently continues to pass between the layers of the middle coat until it meets a softened and atheromatous patch, and then again bursts into the canal of the artery. In this form of the disease, the patient may live for years after the occurrence of the rupture; the new channel that the blood has taken becoming lined with a dense, smooth membrane, and resembling closely the interior of the artery, from which, however, it is separated by a kind of septum. The appearance here presented by the vessel has occasionally been erroneously described as constituting a double aorta. 3. The blood may find its way between the laminae of the middle coat, but does not escape further by rupture of the external, or by the giving way of the lining membrane of the vessel. A sac is consequently formed in the substance of

Fig 444 Rupture of Lining Membrane of Aorta, giving rise to a Dissecting Aneurism which burst into Pericardium. Aorta much dilated and covered with Calcareous Plates, except where the Aneurism occurred; there it was atheromatous.

the middle coat, which may become chronic, but which will at last rupture externally.

PROCESS OF FORMATION OF AN ANEURISM.—The progression of the changes leading to the formation of an aneurism is briefly as follows. The artery having been affected with chronic endarteritis, a patch of atheromatous softening forms, and the lining membrane covering it, perhaps with a portion of the inner layers of the middle coat, becomes eroded; or the walls of the vessel may be weakened at this point without any destruction of their coats. Cohesion, however, takes place between the tissues of the vessel at the eroded or weakened spot; and the outer coat becomes strengthened and thickened by the formation of dense fibroid tissue. Dilatation next takes place at this point; if of the entire coats, a *true* aneurism is formed; if of the eroded tunics, a *false* aneurism occurs; but if no cohesion have previously taken place between the different coats of the vessel, the blood becomes effused into and between them, thus constituting a *dissecting* aneurism.

STRUCTURE OF AN ANEURISM.—An aneurismal sac, if it be composed of a dilatation of all the coats of an artery, may be recognized on dissection by the atheromatous and calcareous patches which are met with in the tissues of which it is composed. If it be a false aneurism, it will be found that there is little, if any, of these deposits in the walls of the sac; that the middle coat usually terminates abruptly at its mouth, and that the external coat is greatly thickened and strengthened by newly formed fibroid tissue. An aneurismal sac may vary in size from a tumor not larger than a cherry to a growth of the magnitude of a coconut or large melon. The mouth, which is oval or round in shape, varies greatly in size, being always very small in proportion to the sac. Usually the interior of an aneurismal sac contains a quantity of colorless fibrin, arranged in concentric laminae of but moderate thickness; these laminae of fibrin are of a pale-buff color, dry, and somewhat brittle where they are most closely applied to the wall of the sac; the more external were first deposited, and occasionally are found to have undergone a kind of fatty degeneration; as we approach the interior of the vessel, they become softer and more colored, and at last, in the central portions, dark masses of coagulum are often met with.

This colorless laminated fibrin was termed by Broca the *active* clot, as it is deposited only when the blood is in motion in the sac of the aneurism. It is formed in the same way as a colorless thrombus in a diseased vein (see p. 80), the first step in the process being the adhesion of a layer of white corpuscles to the diseased surface of the aneurismal sac. These disintegrate, and thus determine the formation of a layer of fibrin. The microscopic examination of recent laminated clot shows the presence of numerous white corpuscles which have escaped disintegration between the layers of fibrin. It is thought by some physiologists that possibly these are of a different nature to those which take part in the process of coagulation. In the older layers of clot no corpuscles are recognizable, but much fatty and granular matter is always found, which may have resulted from their disintegration. The part played by the adhesion of the corpuscles in the formation of laminated fibrin explains the influence of retardation of the blood-stream on its formation. In fusiform aneurisms in which the flow of blood is rapid throughout the dilated vessel, adhesion takes place with difficulty, and no clot is usually found, while in sacculated aneurisms in which the movement of the blood is necessarily much slower, laminated fibrin is always abundantly deposited. It will be afterwards seen that those modes of treatment by which the flow of blood through the sac is retarded, exert the most powerful influence in determining the deposit of layers of clot. The color of the clot varies in different cases; the more rapid the flow of blood, the fewer red corpuscles will be entangled in the coagulum, the slower it is the darker the clot will be. Complete arrest of the circulation leads to the formation of an ordinary dark blood-clot,

exactly like that produced when blood, withdrawn from the body, is allowed to coagulate. Clot of this kind is always found post-mortem in the middle

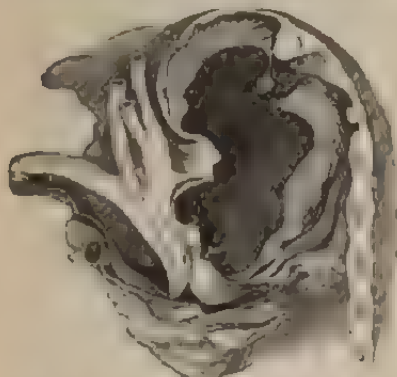

Fig 445.—Large Aneurysm of Ascending Aorta, projecting against and protruding outwards the ribs. Layers of Laminated Fibrin arranged in the direction of the Current of the Blood.

of the sac of the aneurism, and is then formed probably immediately before or after death. Those modes of treatment which completely arrest the flow of blood into the sac cause the formation of a similar conglutium. It is the *passive* clot of Broca.

The layers of fibrin in the laminated clot are more or less concentrically arranged, but no single lamina reaches over the whole sac. The older layers bear evidence of having been formed when the sac was smaller and subsequently flattened out against the enlarged walls of the sac (Fig. 445). The deposit of laminated fibrin exerts a powerful influence in preventing the too rapid increase of the tumor. The lining of the walls of the sac with such a tough and elastic material as the stratified fibrin, must greatly tend to deaden and break the force of

the wave of blood that is projected against what would otherwise be an unprotected membrane. Another great purpose it serves is to lessen the capacity of the sac, and thus to diminish the pressure on surrounding parts, the distending force of the aneurism being proportional to the area of the sac as well as to the force with which the blood is driven into it. In those cases in which the laminated fibrin is small in quantity or altogether deficient, the aneurismal tumor rapidly increases with a forcible pulsation that is not met with in other circumstances. The dark coagulum or passive clot of Broca is a less efficient support to the wall of an aneurism than the colorless or active clot. It is much softer in consistence, and at first contains a considerable amount of serum; this gradually squeezes out as the clot contracts and thus it becomes considerably diminished in bulk. If the clot completely fills the sac this contraction may possibly be followed by the reestablishment of a cavity, but the experience of some of the modern modes of treatment shows that it is not very likely to occur, the contraction of the clot being accompanied by a corresponding diminution in the size of the sac, chiefly due to the pressure of the surrounding structures. The clot further diminishes from the disintegration of the red corpuscles which form the chief part of its bulk. As this takes place it becomes decolorized, and thus, if the sac is only partly filled by a dark clot, this becomes flattened out and finally forms a layer indistinguishable from the laminae of colorless fibrin.

Pressure effects. As the sac of an aneurism enlarges, it exerts injurious and often fatal effects by its pressure upon contiguous parts. These pressure-effects deserve attentive study, as they constitute an important and, in some instances, the sole element in the diagnosis of aneurism. The pressure on the surrounding parts increases with the size of the sac. Dr. W. H. Stone thus describes the influence of increase in size on pressure. "The hydrostatic force rises rapidly as the sac enlarges; in fact in a modified geometrical ratio as against a simple arithmetical increase of the heart's impulse. We are thus from the first being ground, and the malady is gaining on us according to some simple function of the fundamental law of equality of pressure in all directions. Haughton estimates the hamostatic pressure of the blood in the

human arteries as equal to a column of 9.923 feet. Taking the aneurism as of 3 inches in diameter, its internal surface will be 28.27 square inches, which gives a tension of 12.24 pounds. If the sac rises to 4 inches diameter, this increases to 50.26 inches of surface and to a tension of nearly 25 pounds."

One of the most common pressure-effects of aneurism is the occurrence of œdema of the limb or part, owing to the compression exercised by the tumor upon the large and deep *venous trunks* in its vicinity. The consequent obstruction to the venous circulation in the interior of the limb may give rise also to a distended or varicose condition of the subcutaneous vessels, and in some instances it may even go on to the production of gangrene. The pressure of the sac, also, on neighboring *arteries*, or even on the upper part of the very vessel from which it springs, and its interference with the general capillary circulation of a part, is commonly associated with compression of the veins, and may considerably increase the ill-consequences resulting from it. The pressure upon a neighboring artery may go on to perforation of the vessel by the sac, and so a communication between the two may be set up; thus aneurism of the aorta has been known to perforate and communicate with the pulmonary artery. By its pressure upon neighboring *nerves*, an aneurismal sac may give rise either to great pain in the part supplied by them, or to disturbance of their function; the nerves themselves becoming in some cases, expanded or flattened out, and ribbon-like (Fig. 446), and in other instances tortuous and wavy, being considerably elongated. The pain in the nerves is often one of the earliest signs of the existence of an aneurism. The pain is usually of two kinds: it is either lancinating and radiating along the course of the nerve that is compressed; or, when the tumor presses severely upon neighboring parts and tissues, more especially if it give rise to erosion of the bones (as in Fig. 445), an aching, burning, tearing, or boring sensation is often experienced in the part subjected to the pressure. In other cases, again, important modifications in the function of parts take place, in consequence of the pressure that is exercised upon their nerves. Thus, for instance, the compression of the recurrent laryngeal nerve will occasion hoarseness of voice and difficulty of breathing, depending on spasm or paralysis of the abductors of the vocal cords. On the *bones* an aneurism may produce very important effects by its pressure, often eroding deeply the osseous tissue. If the bone be a flat one, as the sternum, the aneurism may perforate it by making as smooth and round a hole in it as if this had been worked by the trephine. *Glandular organs and their ducts* in the neighborhood of aneurisms suffer the most injurious effects from the pressure of these tumors, their functions being arrested, and the passage of their secretions interfered with; so, also, by the pressure exercised on the *trachea* and *œsophagus*, respiration and deglutition may be seriously impeded.

NUMBER.—Aneurisms, though usually single, are not very unfrequently multiple. There may be more than one tumor of this kind in the same limb; thus the iliac and femoral arteries on the same side may both be affected. In other cases, corresponding arteries in opposite limbs are the seat of aneurism; thus the two popliteals are not unfrequently found to be the seat of this disease, and occasionally an aneurism may exist in

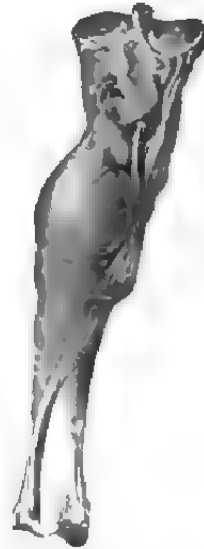

Fig. 446. — Flattening and stretching of Posterior Tibial Nerve by pressure of an Aneurism of the Calf.

one of the limbs and others in the arteries of the interior of the body. Numerous aneurismal tumors are at times met with in the same person: thus, Peletan records a case in which no fewer than sixty-five were observed.

DURATION.—The duration of an aneurism varies very greatly. In young full-blooded persons it often makes progress with great rapidity; whereas in elderly people of feeble constitutions, in whom it is accompanied with more or less debility of the heart's action, the disease may assume a very chronic form; thus, Hodgson relates the case of an aneurism of the femoral artery of twenty years' duration. Much also will depend on the situation of the aneurism, the size of the mouth of the sac, and the relation of the sac to the impulse of the blood into it, the larger and more direct the mouth of the tumor, the more readily will the blood be projected in it at each impulse of the heart, and the more quickly will the tumor expand.

SYMPTOMS.—The symptoms of an aneurism are of two kinds. 1. Those that are peculiar to this disease; and 2. Those that are simply dependent on the presence of the tumor occasioned by the enlarging sac. The peculiar or pathognomonic signs are those that are dependent on the communication of the sac with the artery; they consist of signs afforded by the manual and auscultatory examination of the tumor; those that are dependent on the mere size of the growth are the pressure-effects. It is of course only in external aneurisms that those signs which are ascertainable on manual examination of the tumor can usually be recognized. In internal aneurisms, in the majority of cases, the auscultatory signs and the pressure-effects afford the best indications of the presence and nature of the tumor; though, when this approaches the surface, much information can be gained by palpation.

Symptoms of External Circumscribed Aneurism.—The tumor is usually round or oval, distinctly circumscribed, and situated upon and in close connection with some large artery. It is at first somewhat compressible, but afterwards becomes more and more solid as fibrin is deposited in it. The most marked sign is, perhaps, the *pulsation* that is felt in it from the very first. This is of a distensible, eccentric, and expanding character, separating the hands when laid upon each side of the tumor, by a distinct impulse from within outwards. The pulsation is most forcible in an aneurism in which there is but little laminated fibrin; and as this increases in quantity the pulsation gradually loses its tense, expanding character, being converted into a dead *thud*, and in some cases ceasing entirely. When pulsation is obscure, the compression of the artery below the sac will cause it to become more distinct, or it may be increased in distinctness by elevating the limb or part affected. When the artery above the sac is compressed, the flow of blood into the tumor is necessarily arrested, and a considerable quantity of its more fluid contents may be squeezed out by gentle pressure. If the hands be then laid upon each side of the tumor, and the pressure suddenly taken off the artery, the blood will be found to rush into and distend the sac by a sudden stroke, separating the hands from one another. This may be looked upon as one of the most characteristic signs of aneurism.

The *bruit* or *sound* emitted by the blood in its passage through an aneurismal sac was first noticed by Ambrose Pare. It varies much in character, being usually loud, rasping or sawing—loudest and roughest in tubular aneurisms. Occasionally the bruit is double, and if so, it clearly indicates the sacculated nature of the aneurism. It is possible however, that when great aortic regurgitation is present, the backward current of blood in the large vessels might give rise to a feeble diastolic murmur in a fusiform aneurism. In many cases it is altogether absent; this especially happens in sacculated

aneurisms with small mouths, or in those that are much distended with coagula and blood. The absence of sound, therefore, in a tumor must not be taken as a proof that it is not an aneurism. The sound is usually best heard in aneurisms that are not too fully distended with blood; indeed, it is usually most distinct when the sac is partially emptied. Thus, for instance, it not unfrequently happens that, in an aneurism of the ham or thigh no bruit, or but a very faint one, is audible so long as the patient is standing; but if he lie down, and elevate the limb so as partly to empty the sac, then it may be distinctly heard. Another sign of considerable importance consists in the *diminution in the size of the tumor*, and the *cessation of the pulsation and bruit on compressing the vessel* leading to the sac, and the immediate and sudden return of these signs on removing the pressure from the artery.

Many of the symptoms that have just been described are peculiar to and their combination is characteristic of aneurism, being dependent on the communication that exists between the artery and the sac. Those that result from the pressure of the sac upon neighboring parts are common to aneurism and to any other kind of tumor; but, though not of so special a character as those that have just been described, they are of considerable importance in determining the nature of the disease when taken in conjunction with the other symptoms.

Symptoms of Diffused Aneurism.—When a sacculated circumscribed aneurism becomes diffused, the sac having given way, but the blood being still bounded by the tissues of the limb, the patient experiences a sudden and acute pain in the part, and usually becomes pale, cold, and faint. On examination, it will be found that the tumor has suddenly and greatly increased in size, at the same time that it has lost its circumscribed and distinct outline. The pulsation and bruit become materially diminished in force and in distinctness, having receded as it were from the surface, and may disappear altogether. The limb may also become œdematous, or may suffer in other ways from the diffused effects of the pressure of the aneurismal swelling upon the neighboring veins and tissues. At the same time, the circulation in it being greatly obstructed, the limb may become cold and livid, and a sensation of weight and general inutility will be experienced in it. In these circumstances the aneurismal swelling usually becomes harder, in consequence of the coagulation of the blood in the areolar tissue around the sac; by which, indeed, the further extension of the disease is arrested, and a fresh boundary is often formed, so as to limit the extravasated blood. If it be left to itself, the tumor will now usually increase rapidly in size, sometimes without, sometimes with much pulsation, so that at last it may so obstruct the circulation through the limb as to occasion gangrene. The tension caused by the rapid increase of the tumor excites more or less acute inflammation in the surrounding structures. As it advances towards the surface, the skin covering it becomes thinned and reddened, the tumor becomes soft and semi-fluctuating, owing to the coagulum breaking down, and eventually external rupture will ensue.

In some cases it happens that, when rupture of the sac takes place, the effused blood, instead of being limited by the surrounding areolar tissue, becomes suddenly and widely extravasated into the substance of the limb. When this untoward accident happens, the shock and local disturbance are very great, and the patient is suddenly seized with a very severe lancinating and numbing pain in the part. The pain is most severe in those cases in which the rupture takes place under the deep fasciæ, by which the effused blood is tightly bound down; and it may be so severe as to occasion syncope. In other instances, faintness occurs from the sudden escape of blood from the current of the circulation into the substance of the part, being most

marked in those instances in which the blood is suddenly and largely effused into the areolar tissue. If the extravasation happen in a limb, this will become greatly swollen, hard, brawny, and cold. The superficial veins are congested, and the circulation in the lower parts of the member is soon completely arrested by the pressure of the extravasated and semi-coagulated blood upon its vessels, more particularly the large venous trunks. In consequence of this, gangrene of a moist kind usually makes its appearance, and speedily destroys the patient's life.

DIAGNOSIS.—The diagnosis of aneurism may in many cases be effected with the greatest possible ease by a student in surgery; in other instances it requires a vast amount of care, and the most experienced judgment, to come to a correct conclusion as to the nature of the tumor. This is easily done when the aneurism is superficial, recent, and circumscribed, the blood in it being fluid, and all the signs of the disease well marked. The diagnosis is often replete with difficulty when the aneurism is deeply seated, or, if external, when it is old and filled with coagula; also, if acute inflammation or suppuration have taken place about it, or if it have become diffused.

In effecting the diagnosis of aneurism we have, in the first place, to ascertain the existence or absence of a tumor: and, after this has been done, to ascertain whether it be aneurismal or of some other character. Both points, the latter especially, are difficult to determine in internal aneurisms: in the external, the doubt is not as to the presence of a tumor, but as to its nature. The tumors with which aneurisms may be confounded may conveniently be divided into two classes—those that do and those that do not pulsate.

Every pulsating tumor is not an aneurism. Thus there may be pulsation in various kinds of *encephaloid tumor* or *soft sarcoma*, or in *growths composed of nervous tissue*. In such cases as these, many of the signs of aneurism are present; thus the size of the tumor may be diminished by compression, and the distinct influx of blood into it may be felt on the removal of the pressure, the tumor returning to its original size with a soft swelling pulsation; there may also be a bruit, often of a loud and distinct character. But these tumors may generally be distinguished from aneurisms in not being quite so distinctly circumscribed—in being soft, spongy, and elastic, without the sensation of fluid that is met with in some forms of aneurism, or of solid coagula that occur in others. Again, the bruit is either soft, blowing, and more prolonged, or else sharp and superficial; the pulsation, also, is not so distinct, and is more of the nature of a general swelling and heaving of the tumor than of a distinct thump. Much light is occasionally thrown upon these affections by their being met with in situations where aneurism cannot occur, from the absence of any arteries of sufficient size to give rise to it, as, for instance, on the head of the tibia or the side of the pelvis; but if a tumor of this kind be situated upon or under a large artery in the usual site of an aneurism, then the diagnosis is certainly replete with difficulty, and cannot indeed in many cases be made. Several instances have occurred, in which Surgeons of the greatest skill and experience, as Guthrie and Stanley, have ligatured arteries on the supposition that they had to do with aneurism, when in reality it was one of the pulsating tumors just mentioned that closely simulated it.

Pulsation may be communicated to a tumor of a fluid character seated upon an artery; here the diagnosis, though often difficult, is more readily made than in the last case. Attention to the history of the case, to the impossibility of diminishing the tumor by pressure, either directly upon it or on the artery leading to it, its fluctuation, and want of circumscription, will usually point out its nature. Especial attention should likewise be paid to the facts that the pulsation is a distinct heaving up and down of the tumor,

and neither eccentric nor distensile, and that the swelling may often be wholly or partly separated, by raising it up, from the artery lying beneath it. By attention to these points, abscesses in the axilla, under the pectorals, at the root of the neck, and in other situations where pulsation may readily be communicated to the fluid mass, can be distinguished from aneurisms; yet errors in diagnosis have happened, and will continue to do so, from the intrinsic difficulty of these cases, and from no want of skill or care on the part of the Surgeon; and those will be most charitable in their criticisms of the mistakes of others, who have most frequently had occasion to experience these difficulties in their own practice.

Tumors that do not pulsate, either by their own vessels or by those that lie beneath them, are not so readily confounded with aneurism as the class of affections that has just been described. Yet it must be borne in mind, that in some instances even aneurisms do not pulsate, or but very indistinctly so, having become filled with a dense and firm coagulum. The non-pulsating tumors that chiefly require attention are *glandular or thyroid swellings*, seated over the carotid artery at the root of the neck or in the popliteal space. If these be of a fluid character, their fluctuating unvarying size, and the want of position in them, sufficiently indicate that they are not connected with the artery, from which they may also frequently be separated, and upon which they may be distinctly moved. If solid, they are usually irregular and nodulated on the surface, and can frequently be detached by the fingers being passed underneath them and raising them from the subjacent vessel. There is much danger of mistaking a consolidated aneurism which is undergoing or has undergone spontaneous cure, and in which there is consequently no pulsation, for a solid tumor of some kind. I have known one instance in which the thigh was amputated for a very painful solid tumor of the popliteal space, which proved on dissection to be a consolidated aneurism pressing upon the posterior tibial nerve. Fig. 447.

Aneurisms, more particularly those that are diffused, have not unfrequently been mistaken for *abscesses*; and it is no very uncommon thing for a Surgeon to be called to an aneurism which, under this supposition, has been frequently pointed, or painted with iodine. I have twice ligatured the external iliac for aneurisms of the groin that had been mistaken for abscesses. Occasionally, the more fatal error has been committed of puncturing the tumor with the view of letting out pus, when none appeared, and, either immediately or after a lapse of a few hours, profuse arterial hemorrhage ensued. That this accident may arise from the intrinsic difficulties of the diagnosis is evident from the fact that it has happened to such Surgeons as Desault, Pott, Dupuytren, Progl, and many others. I have once seen

Fig. 447.—Section of Aneurism of Calf, undergoing spontaneous cure, mistaken for Tumor. Limb amputated. (a) Black recent Coagulum lying in centre of Laminated Fibrin (b) Posterior Tibial Nerve stretched

this accident occur to a Surgeon of considerable experience, who, mistaking a diffused popliteal aneurism for an abscess, opened it with a bistoury, but finding no pus, applied a poultice; alarming hemorrhage ensued in about forty hours, and I amputated the thigh on the second day after this untoward occurrence.

The difficulty in diagnosis is especially apt to occur in those aneurisms which, having become diffused, have ceased to pulsate, have no bruit, are elastic, softened, and diffident to the feel, and in which the skin has become reddened and inflamed by pressure from within. It is only by careful attention to the history of the case, and by skilful manipulation, that the true nature of the tumor can be made out. But an aneurism may actually become associated with an abscess in one of two ways. Thus it may suppurate, the inflammation taking place in the areolar tissue around it, with swelling, redness, oedema, and heat of the integumental structures, increase of size in the tumor, and probably solidification of it. If this abscess be opened or allowed to burst, dark grumous pus will escape, followed by coagula and masses of broken-down decolorized fibrin, and sometimes accompanied, but more usually followed after a lapse of some hours, by a free and perhaps fatal discharge of florid blood.

Another form of combination between abscesses and aneurism consists in the opening of an artery by ulceration into the cavity of an abscess, so that the blood is projected directly into this from the opened vessel. In cases of this kind — of which the instance that occurred to Liston is a good example — we have the ordinary signs of abscess, usually of a chronic character, to which those of an aneurism are generally superadded suddenly, with great increase in the bulk of the tumor. This accident has been observed chiefly in abscesses of the neck, opening up a communication with the carotid artery.

With **rheumatism and neuralgia** it would at first appear to be difficult to confound an aneurism, but in practice it is not so. I have known several cases in which the lancinating pains of aneurism, more especially when the tumor was internal, have been mistaken and treated for rheumatic or neuralgic affections; and I have even known the pain occasioned by the presence of a large aneurism of the thigh treated for several weeks as rheumatism. In a large proportion of popliteal aneurisms the patient first presents himself complaining of rheumatic pains in the knee; in fact so frequently is this the case that it is a good rule whenever a patient complains of obscure pain in that joint, to examine the ham for an aneurism as the first step in making a diagnosis. In such cases as these, it is of course obvious that a little care and proper examination will usually serve to enable the Surgeon to avoid an error. The aneurismal may be distinguished from the rheumatic pain by its having a twofold character — being both lancinating and intermittent, as well as continuous, aching, and burning. When this kind of pain is persistent, especially about the back, the side of the head and neck, or arm, it ought always to cause the Surgeon's attention to be directed to the condition of the neighboring large vessels.

TERMINATIONS — Spontaneous Cure of an aneurism is of very rare occurrence. The manner in which it happens has been especially and ably studied by Hodgson, and more recently by Bellingham; and the pathology of this process is of considerable interest, from its bearing upon the cure of the disease by surgical operation. The spontaneous cure may accidentally, though very rarely, occur by inflammation of the aneurism and consequent obliteration of the artery (see Suppuration of Sac); but most frequently it is by the gradual deposition of laminated fibrin in the interior of the sac that it is filled up completely. This process usually takes place in aneurisms affecting arteries of the second or third magnitude, rarely in those of the aorta, though both

Hodgson and Broca have met with instances; and it can happen only in sacculated aneurisms, the fusiform not admitting of it, it being necessary that the blood flowing through the sac be somewhat retarded in its passage, so as to favor the deposit of its fibrin upon the interior of the tumor. This process, which is a very different one from the simple coagulation of the blood, is the increase of a natural condition always going on in the sac. In all cases of sacculated aneurism, there is a tendency to the production of a spontaneous cure, though this is rarely accomplished. The tendency to it is shown by a contraction and partial occlusion of the artery *below* the sac, and the consequently diminished force of the circulation through it, by which the deposition of fibrin is greatly increased, at the same time that the collateral vessels given off *above* the sac often enlarge to a considerable extent, and thus divert from it blood which would otherwise have passed through it. This condition of the vessel below the sac may be looked upon as the first and most important step towards the consolidation of the tumor. The process is also materially assisted by the mouth of the sac being small, and so situated that the blood cannot be directly driven into it.

For spontaneous cure to take place, it is by no means necessary that the whole current of blood should be suddenly arrested. If such an accident occur, the aneurismal sac becomes filled with a large dark soft clot, which may yield, if from any cause a pulsating stream of blood be again admitted, but which under favorable circumstances may lead to a complete cure. If blood continue to circulate through the sac, deposit of laminated fibrin will take place if the impetus with which this fluid is sent into the tumor be considerably diminished. This may happen from the occurrence, in the distal portion of the artery or the mouth of the sac, of some one or other of those conditions that have already been described. So, also, it has been found that in those cases in which two aneurisms are situated upon one artery, the distal one is very apt to undergo partial or even complete consolidation, the blood losing its impetus in its passage through the first sac. Any constitutional cause or condition also, by which the impulse of the heart is lessened, and the force of the flow of blood through the sac diminished (as the occurrence of phthisis), will greatly favor the deposit of laminated fibrin and the consolidation of the tumor.

As the aneurism undergoes spontaneous cure, the pulsation in it gradually becomes more and more feeble, until it ceases entirely; the bruit proportionately lessens, the tumor becomes harder, and at last completely consolidated; at the same time, the anastomosing circulation is sometimes found to be established in some of the collateral vessels of the limb. Eventually, the solidified tumor shrinks in size, undergoing gradual absorption, with ultimate conversion into a small mass of fibroid tissue.

Suppuration with sloughing of an aneurismal sac is not of very frequent occurrence, but is especially apt to happen in those cases in which the tumor has increased rapidly, or has suddenly become diffused, and thus is exerting great pressure and causing severe tension of the surrounding parts. The accident is not uncommon, also, after operations undertaken for the cure of aneurism in which the wound comes in close proximity to the sac. The inflammation is then merely an extension from that in the wound, and is usually dependent upon septic contamination. Though the process is usually spoken of as suppuration of the sac, the inflammation commences in the tissues surrounding the aneurism, the sloughing of the sac itself being a secondary process dependent upon its nutrition being cut off by the pus that forms around it. Suppuration is peculiarly liable to happen around tumors of a large size that have become partly diffused, that are filled with masses of decolorized fibrin, and that are situated in places where the areolar tissue

is abundant and lax, as in the axilla. The symptoms of this condition impending are swelling, tension with heat, throbbing, and redness of the parts around the tumor; the integuments covering it put on pressure, and are evidently deeply inflamed, at the same time that there is a good deal of fever and general constitutional disturbance. As the suppuration advances, the ordinary signs of acute abscess occur; the skin covering the tumor becomes red and livid at one part, where pointing takes place; and if the Surgeon make an incision into it, or if the tumor burst as assuredly it will if left to itself, a quantity of pus mixed with large masses of broken-down coagula will be let out. The discharge of the contents of the aneurismal sac, may be followed by so profuse a gush of arterial blood that the patient is suddenly exhausted.

Occasionally, however, as a consequence of the inflammation of the surrounding tissues, the artery becomes firmly plugged by a thrombus above and below the opening into the aneurism before the sac gives way, and thus hemorrhage may be prevented and a spontaneous cure result, the cavity closing like an ordinary abscess after the sloughs and the broken-down clots have been discharged.

Causes of Death from Aneurism.—An aneurism may prove fatal in various ways. It does so when internal, most frequently by *pressure* on parts of importance in its vicinity, the patient being destroyed by the exhaustion induced by interference with their functions; this is usually the way in which aneurisms of the aorta occasion death. In other cases the sac bursts into the pericardium, pleura, or peritoneum, and sudden death may occur from loss of blood; or asphyxia may result from its giving way into the trachea. Then, again, death may result by the occurrence of *syncope*, more especially if the aneurism be of large size, and situated near the root of the aorta. *Embolism* of the cerebral arteries may occur in consequence of the detachment of a clot. External aneurism most commonly proves fatal by *rupture of the sac*; this may either take place into the interior of a limb, giving rise to one or other of the diffused forms of aneurism, and terminate fatally by the induction of syncope or gangrene; or an aneurism may kill by rupture occurring externally, on one of the surfaces of the body.

The rupture of an aneurism is not always immediately fatal, the aperture in the sac being plugged up by a mass of coagulum, as happened in the case shown in Fig. 448; on the gradual detachment of the deeper portions of which the bleeding may recur in small quantities at intervals, and more or less speedily carry off the patient. On the mucous surfaces, as of the oesophagus or trachea, rupture occurs in a similar manner (Fig. 448). On the serous surfaces, as into the pleura or pericardium, the aneurism may burst by a fissure or by a stellate opening (Fig. 449) forming in the membrane. An aneurism has been known to give way and discharge blood for some weeks before it proved fatal; and it may even happen that, after the rupture has occurred, no hemorrhage may take place, but death may result from the pressure of the tumor. Thus, in the case of Liston, the sac of the aneurism which caused the death of that great Surgeon, had actually given way, a mass of coagulum projecting from it into the trachea; yet death resulted from the irritation induced by pressure upon the inferior laryngeal nerve, and not from hemorrhage.

TREATMENT.—The treatment of aneurism is of two kinds—constitutional and local. In many cases, as in the various forms of internal aneurism, for instance, the constitutional treatment can alone be employed; and in all cases of external aneurism it should be had recourse to as an important adjunct to any local measures that are adopted.

In the **Constitutional or Medical Treatment** of aneurism, the great object

3. **Distal Ligature.**—In some cases in which the ligature cannot, for anatomical reasons, be applied on the proximal side of the aneurism, as in the arteries about the root of the neck, it was recommended by Brasdor, a French Surgeon, about the middle of the last century, that the vessel should be tied on its *distal* side. This operation, originally proposed by Brasdor, was first performed by Deschamps in 1799 at la Charite in Paris in a case of femoral aneurism. In principle, it resembles the Hunterian operation, the object being to arrest so much of the flow of blood through the sac that the consolidation of this may take place in the usual way, by the deposit of laminated fibrin. In the Hunterian operation, this is effected by deposit from the lessened quantity of blood that flows through the sac; in the distal operation it is sought to be accomplished in the same way, and the success of the operation must necessarily depend, in a great measure, upon the extent to which the flow of blood through the sac is interferred with. This operation, however, is rarely successful; for, independently of the ordinary dangers resulting from the application of the ligature to a large vessel, the sac will continue to be distended with, and to receive the direct impulse of, the blood that is driven into it. The natural result of the ligature would be, therefore, to increase the tension of the sac, but as Holmes points out, the enlargement of the collateral circulation opens, as it were, "side-slucies" to relieve this pressure, and consequently after a few hours or days the sac is usually found to be less tense than before the operation. Hence the progress of the aneurism may be arrested for a time, but it will often speedily increase again, and may perhaps eventually destroy the patient by supuration and sloughing. Of 38 cases in which this operation was practised on the carotid artery, in 25 instances a fatal result more or less speedily followed the operation; in the remaining 13 cases the patients survived the effects of the ligature of the artery, though in very few if any cases were they cured of the disease for which the operation was practised. This operation will be considered more in detail in speaking of the particular cases in which it has been practised—*vide* Chap. xlv.

Indications and Contra-indications of Ligature.—Ligature of an artery for aneurism, by the Hunterian method, succeeds best in those cases in which the tumor is circumscribed, of moderate size, slow in its growth, having a tendency to consolidation, and unaccompanied by much oedema of the limb. When the aneurism is undergoing spontaneous cure, no surgical interference should be employed, but the case left to nature. In this way it occasionally happens, during the preparatory treatment of the disease, that the aneurism becomes consolidated.

Before the Surgeon proceeds to cut down upon an artery with the view of tying it, he should, as far as practicable, ascertain by a careful examination of it, whether it appears to be in a healthy and sound state, at the point at which he is about to tie it. He should feel along its course to ascertain if it be smooth, easily compressible,

Fig. 453.—Femoral Artery ligatured for Popliteal Aneurism obliterated at *a*, the site of the Ligature, and at *b*, where the Tumor has become consolidated and absorbed, between these points the Artery is open, and collateral branches are enlarged.

a gradual and careful manner, so that the tendency to the deposit of laminated fibrin might be increased. Valsalva endeavored to carry out the first of these objects by subjecting the patient to small and repeated bleedings, and by gradually reducing the quantity of food that was daily taken, until it was lowered to half a pound of pudding in the morning, and a quarter of a pound in the evening. In this way the patient's strength was reduced until he could scarcely be raised up in bed without fainting; the quantity of food was then gradually augmented, so that the plasticity of the blood might be restored. It is seldom that Surgeons carry out Valsalva's plan of treatment in the precise manner indicated by him; it is generally found to be more convenient to modify it somewhat according to the circumstances of the case, though the principles on which it is conducted are essentially the same.

In adopting any constitutional treatment in cases of aneurism, the first and most essential point to be attended to is, to keep the patient perfectly quiet in bed and free from all mental, emotional, or conversational excitement. The diet should at the same time be very carefully regulated, being gradually reduced in quantity, and being made to consist principally of farinaceous food, with but a very small quantity of meat, but little liquid, and a total absence of all stimulants. Perhaps the best regimen is that recommended by Bellingham, consisting of two ounces of bread and butter for breakfast, two ounces of bread and the same quantity of meat for dinner, and two ounces of bread for supper, with about two ounces of milk or water with each meal, or occasionally sipped in small quantities. At the same time purgatives should be administered, especially such as give rise to watery stools, and remove obstructions of the portal system; with this view a scruple of the compound jalap powder may be given twice a week. In some cases, if the heart's action be particularly strong, recourse may advantageously be had to small bleedings from time to time.

Iodide of potassium, in doses varying from five to thirty grains three times a day, has been largely used in cases of intrathoracic and abdominal aneurism, especially by Chuckerbitty, G. W. Balfour, and W. Roberts, and its good effects lend some weight to the supposed syphilitic origin of many aneurisms. In a large proportion of the cases thus treated, the sufferings of the patients have been relieved; there has been diminution of the size of the sac, and in several instances the cure has been apparently perfect. The enforcement of the recumbent posture is, as Balfour rightly insists, of high importance as an adjuvant in this treatment. There certainly appears to be sufficient evidence to warrant a trial of the iodide in the constitutional treatment of aneurism.

By judiciously carrying out these plans of treatment and modifying them according to the circumstances of the case, consolidation of the aneurismal tumor may occasionally be produced; or, if this be not attained, the progress of the disease will be very materially retarded.

When aneurism occurs in *old, feeble, cachectic, or anæmic persons*, a lowering plan of treatment is altogether inadmissible; here, the blood being deficient in fibrin, and the system in an irritable state from debility, the best results follow such a course as will improve the plasticity of the blood, and regulate the action of the heart. With this view, complete rest, the administration of the preparations of iron, a dry but nourishing meat diet, and the occasional employment of opiates to relieve pain and to quiet the system, will be attended by the best results. In aneurism occurring in elderly people and amongst the poorer classes, this plan is, perhaps, more successful than any other.

In the **Local Treatment** of aneurism but little can be done with the view of checking its progress, except by the employment of direct surgical means. The application of ice to the surface of the tumor is said to have acted

Porter, however, recommends that the ligature should be applied in such cases, though I cannot but doubt the propriety of this advice. When inflammation has been set up in the sac, with a tendency to suppuration of the tumor, it is a debatable question whether the ligature should be applied or not. In these cases I agree with Hodgson, that the artery should be tied; for even if the sac eventually suppurate, there will be less risk to the patient if this event occur after the application of the ligature, than if it happen while the artery leading into the tumor is pervious. If suppuration have already taken place around the sac, the application of the ligature above the inflamed tumor on the point of bursting would be worse than useless. In such cases, the line of practice must be determined by the seat of the aneurism. If this be in the axilla, groin, or neck, it should be laid freely open, the scragula scooped out, and the artery tied above and below the mouth of the sac—a most formidable and doubtful operation, but the only one that holds out a chance of success. If the aneurism be in the ham or calf, amputation would probably be the best course to pursue.

In some instances, there is no resource left to the Surgeon but to amputate. 1. Amputation must be performed when the aneurism is associated with carious bone or a diseased joint, as when a popliteal aneurism has produced destruction of the knee. 2. If the aneurism have attained so great a magnitude that it has already interfered seriously with the circulation through the limb, as indicated by considerable edema, lividity, and coldness of the part, with distention of the superficial veins, it is a question whether the application of the ligature may not immediately induce gangrene, and whether the patient would not have the best chance of recovery by submitting to amputation at once; this is more particularly the case when the aneurism, whether previously large or small, has become diffused with impending gangrene, when removal of the limb must not be delayed. 3. If gangrene have actually supervened, and the patient's strength be sufficient to bear the operation, amputation should be done without delay. 4. If a diffused aneurism, whether suppurating or not, in the lower extremity, have been opened by mistake for an abscess, there is no resource left but immediate amputation.

The mortality after ligatures of the larger arteries for aneurism is very considerable. Thus, in 256 cases of ligature of the larger arteries for aneurism collected and tabulated by Crisp, it would appear that the mortality amounted to about 22 per cent. And Porta finds that, among 600 cases of ligature of arteries for diseases and injuries of all kinds, the mortality amounted to 27 per cent. It must be borne in mind, that these are collections of reported cases, and that, if the unrecorded cases could be got at, the rate of death would, in all probability, be found to be much higher even than that above stated.

ACCIDENTS AFTER LIGATURE FOR ANEURISM.—The accidents that may follow the application of the ligature in a case of aneurism, are: 1. Secondary Hemorrhage from the seat of ligature; 2, the Continuance or the Return of Pulsation in the Sac; 3, the occurrence of Suppuration and Slaughting of the Tumor, with or without Hemorrhage from it; and 4, Gangrene of the Limb.

1. **Secondary Hemorrhage** from the seat of ligature presents nothing peculiar, and has already been discussed in vol. i. p. 404.

2. **The Continuance or Return of Pulsation** in an aneurismal sac after the ligation of the artery leading to it is an interesting phenomenon, and one that deserves much attention. When the Hunterian operation is successfully performed, though the pulsation in the sac be entirely arrested, a certain quantity of blood continues to be conveyed into and through it by the anastomosing channels, and it is from this that the laminated fibrin is

between the sac and the heart, the tying the vessel was no longer the only hope of cure in this formidable disease.

But the treatment of aneurism was destined to be still further simplified, when Vanzetti showed that, by discarding all instruments and by the simple pressure of the finger on the feeding artery, a coagulum might be formed, on the production of which in the sac the cure of the aneurism essentially depends. And in addition to this, the fact was established, that in some cases adequate compression of the vessel and sac might be effected by simple flexion of the limb. Thus, then, we have had a continuous and progressive process of simplification in the treatment of aneurism, as it has been proved that instrumental compression may be substituted for the ligature, that pressure with the finger or flexion of the limb suffices for the deposition of that coagulum on which the cure of the disease depends and, still more recently, the sphere of the applicability of compression has been greatly extended by conducting it during prolonged anesthesia.

Another subsidiary means of treatment in the management of some of the more intractable forms of aneurism, is electro-puncture, by which, as Cuscelli and others have shown, partial consolidation of the contents of an aneurism may be effected so as to retard the progress of the disease, if not to cure it radically.

We will now proceed to consider in detail these various methods of treatment. They are as follows: 1. Laying open the sac; 2. Ligature of the artery on the cardiac side; 3. Ligature of the artery on the distal side; 4. Compression by instruments; 5. Digital compression; 6. Compression by the elastic tourniquet; 7. Flexion of the limb; 8. Acupressure; 9. Manipulation; 10. Galvano-puncture; 11. Injection of the sac with coagulating fluids.

All these various methods of treatment, however they may differ in their details, have, with the exception of the first, the same great principle in view, viz., the consolidation of the aneurismal tumor by the deposit of coagulum within it. When the process adopted is of such a nature as to lead to the slow deposit of coagulum, this will be found to be pale, firm, and laminated, the *active* clot of Brown. When the deposit is rapid, it will be dark, soft, and homogeneous, the *passive* clot.

LIGATURE. The application of the ligature to the feeding artery on the cardiac side of the aneurism, was almost the only method adopted by Sur-

geons for the cure of the disease up to a recent date. The manner in which the ligature should be applied, and the various cautions respecting its use, have been sufficiently discussed (vol. i. p. 414 *et seq.*). The question as to the part of the vessel to which it should be applied in aneurism, remains for consideration; and this involves some important points.

Situation.—There are three situations in which the ligature may be applied: 1, *above and below the sac, by the old operation*; 2, *on the cardiac side of the sac, by Anel's (Fig. 450) or Hunter's*

Fig. 450—Anel's Operation. Fig. 451—Hunter's Operation. Fig. 452—Wardrop's Operation.

(Fig. 451) operation; 3, *on the distal side of the sac, by Brasdor's or Wardrop's operation (Fig. 452).*

certainly of more common occurrence after operations for carotid aneurism than for any other form of the disease. Thus, of 31 cases in which the carotid artery was tied for aneurism, I find that pulsation in the tumor continued or returned in 9 instances; whereas of 92 cases of inguinal aneurism, in which the external iliac artery was ligatured, the pulsation recurred in 6 cases only, and in several of these it is interesting to note that there were two aneurismal sacs in the same limb—one in the groin, the other in the ham; and that the pulsation, though permanently arrested in the popliteal, recurred in the inguinal aneurism. In the ham and axilla, pulsation occasionally though very rarely recurs. This difference in the frequency of the recurrence of pulsation in different aneurisms, is evidently owing to the different degrees of freedom of communication that exist between the sac and the collateral branches in various forms of the disease; thus in a carotid aneurism, the impulse of the heart may at once be brought to bear upon the contents of the sac, through the medium of the circle of Willis. But, in the case of inguinal, femoral, or popliteal aneurism, the anastomoses, consisting rather of the intercommunications of terminal branches than of open communications between large trunks, are less liable to transmit the blood in a pulsatory stream. For the same reason—the great freedom of the communication between the vessels of opposite sides—the pulsation has more frequently been found to continue uninterruptedly and distinctly, though reduced in force, after the ligature of the artery in carotid aneurisms, than in those in any other situation. The cases in which it returns after the cessation of a few hours only are perhaps as frequent in the groin and ham, as in the neck. In those instances in which the pulsation returns within the first twenty-four hours after the ligature, it usually ceases again in a few days, though it sometimes continues a week or two. When it recurs at a later period, it is apt to last somewhat longer. Compression antecedent to the ligature may so enlarge the collateral vessels as to favor a continuance or return of pulsation. I have once known the pulsation continue, though very much lessened, in a popliteal aneurism, after ligature of the superficial femoral, in a case in which treatment by compression had unavailingly been tried for nearly three months. In another case, in which I tied the external iliac artery for popliteal aneurism, owing to the superficial femoral being too diseased to admit of a ligature, the pulsation ceased completely for a time as I was tightening the ligature, but then returned, and became very marked in a few hours. In this case compression had been continually employed before the artery was tied.

The prognosis of these cases is on the whole favorable, but few of them having eventually proved fatal. Of 26 patients in whom pulsation occurred, I find that three died; and in all of these the fatal result was occasioned by inflammation and sloughing of the sac. In all of the three instances, the pulsation recurred within the first twenty-four hours. When it returns at a more advanced period, there is little risk to the patient, as it is usually readily amenable to proper treatment.

A Secondary Aneurism is of extremely rare occurrence; indeed I believe there are only two unequivocal instances of this affection upon record, both of which took place in the ham; the original tumor having disappeared entirely after operation, the secondary disease made its appearance after a time—six months in one case, and in the other after four years. It is of importance to distinguish between a secondary aneurism and secondary or intermittent pulsation in an aneurismal sac. The term "*secondary aneurism*" should be restricted to those cases only in which an aneurismal tumor appears in the site of a former one, which has undergone consolidation and absorption. The question may be raised, whether aneurisms of this kind are a really secondary or whether they may not originate in the dilatation of

a portion of the artery contiguous to the seat of a former disease. It is certainly not very easy to understand how an aneurismal sac that has once undergone consolidation and absorption can again become dilated into a pulsating tumor; and I think it most probable that, although the consecutive aneurism may be found in the same surgical region as the primary one, it in reality takes its origin from a slightly higher part of the artery, where the same structural change may have been in progress that determined the disease in the first instance at a lower point. Double aneurism thus arising is, indeed, occasionally met with in the ham as a primary disease. I have seen a case in which an aneurismal tumor was situated in the ham, and another at or immediately above the aperture in the adductor muscle: if the artery in such a case as this had been tied before the second tumor had attained any magnitude, we can easily understand how, when this became dilated, it might have been considered to be a new enlargement of the original sac, whereas, in reality, it was nothing more than a new aneurism forming in the close vicinity of the old one.

Enlargement of an aneurismal sac without pulsation, after the ligation of the artery leading to it, is an interesting phenomenon, and one that might cause the true nature of the tumor to be misunderstood, as it closely resembles in its slow and gradual increase the growth of a malignant tumor. It is occasioned by the distention of the sac by regurgitant blood brought into it through the distal end of the vessel, without sufficient force to cause pulsation, though with sufficient pressure to occasion a gradual increase in the size of the swelling.

Treatment of Recurrent Pulsation.—In by far the majority of cases of secondary pulsation, this phenomenon ceases of itself in the course of a few days or weeks from consolidation of the sac, in the same way as after ligation of the artery, by the deposition of lamellated fibrin. This tendency to consolidation of the tumor may be much assisted by means calculated to lessen the force of the impulse of the blood into the sac, such as compression of the artery above the point ligatured, rest, the elevated position, and the cautious application of cold to the part; cold, however, must be carefully applied, lest the vitality of the limb being diminished, gangrene be induced. At the same time, direct pressure may be exercised upon the sac, so as to moderate the flow of blood into it; this has in many cases succeeded in procuring consolidation of the tumor, and may most conveniently be applied by means of a compress and narrow roller. This plan is especially adapted to popliteal and inguinal aneurisms, but cannot so well be exercised upon those situated in the neck. Care must be taken that the pressure be not at first too powerful, lest gangrene result; the object is not so much to force out the contents of the tumor, or to efface this, as simply to restrain and moderate somewhat the flow of blood into it. Should the aneurism be so situated that pressure can be exercised upon the artery above the point ligatured, this should be had recourse to either by the finger or by instrument, and will be both safer and more likely to be effectual than direct pressure. I succeeded in this way in curing a very remarkable case of recurrent pulsation in a popliteal aneurism. The patient, a man about thirty-five years of age, was admitted into University College Hospital for an aneurism, about the size of an orange, in the right ham. Treatment by compression was employed, without any effect being produced in the tumor, for three months. During this period compression was employed in all forms—by Cartel's instrument, the weight, the finger, and flexion. I then ligatured the superficial femoral artery in Scarpa's triangle. The pulsation was arrested in the tumor when the ligature was tied but returned in a slight degree in about an hour, and slowly increased, never becoming at all forcible, but being very distinct.

The ligature separated on the fourteenth day. The limb was bandaged, and a pad applied over the aneurism without any effect; and the limb was raised, but still the pulsation continued. Carte's compressor was again applied to the common femoral artery, and used for about three hours in an intermittent manner, when the pulsation finally ceased.

In the event of the pulsation not disappearing under the influence of pressure, conjoined with rest, dietetic means, and the local application of cold, there are three courses open to the Surgeon: 1, To ligature the vessel higher up; 2, to perform the old operation of opening the sac; and, 3, to amputate, if the aneurism be situated in a limb.

With regard to ligaturing the artery at a higher point, I am not acquainted with any cases that throw much light on the probable success of such an operation. We know that the ligature of an artery high up for secondary hemorrhage, after previous deligation of it, is a most disastrous procedure. But here the conditions are by no means identical with, or even similar to, those that accompany recurrent pulsation. In the case of secondary hemorrhage, there has usually not been time for the full development of the collateral circulation; whereas, in the case of recurrent pulsation, many weeks would probably have elapsed before the second operation would become necessary, so that ample time would be given for the enlargement of the anastomoses; and, besides this, the very occurrence of the return of pulsation may be taken as evidence of an unusually free anastomosing circulation. I think, therefore, that if such a case were by any possibility to occur, in which recurrent pulsation could not be checked by the application of pressure, digital or instrumental, to the artery above the point originally ligatured, aided by the other appropriate local and constitutional means that have been mentioned above, the Surgeon would adopt the proper course by ligaturing the artery higher up—*ex. gr.*, the common femoral or external iliac, if the superficial femoral had been the one previously tied. In the event of this not being thought advisable, he must choose between one or other of the two remaining operations, viz., amputation, or opening the sac. Of these measures, I should certainly prefer amputation, as offering the most favorable chance to the patient. The operation of opening the sac, turning out its contents, and ligaturing the vessel supplying it, is in any circumstances a procedure fraught with the greatest danger to the patient, and full of difficulty to the Surgeon, even when he knows in what situation to seek the feeding vessel. How much greater then must the difficulty be, when he is in uncertainty as to the point at which the artery enters the sac, and cannot know whether there be more than one arterial branch leading into it. In the event, therefore, of all other means failing, and of the pulsation in the tumor continuing, amputation is the only resource left to the Surgeon.

In those situations in which this is impossible, the Surgeon may occasionally attempt the old operation. Smythe, of New Orleans, as a last resource, laid open a subclavian aneurism, for which he had successfully tied the innominate some years before, but failed to secure the artery, and the patient died. Morris, however, has successfully adopted this proceeding in a case of carotid aneurism after ligature of the common trunk had failed; and Berkeley Hill in a case of axillary aneurism after ligature of the subclavian.

Since the introduction of absorbable ligatures into surgical practice, a return of pulsation has in a few cases been due to a restoration of the lumen of the artery after the disappearance of the ligature. This is recognized by the presence of pulsation in the vessel at the point at which it was tied. These cases belong to a different class to those in which the vessel has been permanently occluded, and require different treatment. The artery may be

artery being more readily secured should any such accident happen. The force of the circulation being thus taken off from the aneurismal sac, the cause of the disease would, in Mr. Hunter's opinion, be removed; and he thought it highly probable that, if the parts were left to themselves, the sac, with the coagulated blood contained in it, might be absorbed, and the whole of the tumor removed by the action of the animal economy, which would consequently render any opening into the sac unnecessary."

Hunter's first operation was performed in December, 1785, in a case of popliteal aneurism. The femoral artery was ligatured rather below the middle of the thigh, underneath the sartorius muscle; and from that time his method was almost exclusively employed by Surgeons in the treatment of aneurism, until the introduction of compression in 1842.

The **Effects produced upon an aneurismal tumor** by the ligature of the artery, according to the Hunterian method, deserve careful attention. The immediate effect, on drawing the ligature tight, consists in a cessation of pulsation and bruit in the tumor, which at the same time subsides, becoming partially emptied of its blood. The supply of blood to the limb being in a great measure cut off, it becomes numb and cold, with a diminution of muscular power. The more remote effects consist in an increase of the activity of the collateral circulation, by which the vitality of the limb is maintained. At the same time, and, indeed, in consequence of this, the temperature of the limb often rises, until it becomes higher than that of its fellow.

The consolidation of the aneurismal tumor begins as soon as the ligature is applied, and is usually completed in a few days, by changes taking place within it similar to those that occur in the spontaneous cure of the disease. This important change is effected by the gradual deposit of stratified fibrin in concentric layers within the sac, and occasionally by the sudden coagulation of its contents. For the cure to be accomplished by the deposit of laminated fibrin, it is necessary that, though the direct flow of blood through the tumor be arrested by the ligature of the main trunk, some should yet be carried into it by collateral channels. This is a condition very favorable to the success of the ligature; for, if it happens that all the flow of blood through the tumor is arrested, coagulation of that which happens to be contained in it will ensue, and a soft yielding clot be formed, which is more likely to lead to unfavorable results than the firm products of slow coagulation. It is of importance to observe, that the proper consolidation of the aneurismal tumor, by the deposit of laminated fibrin, will occur even though a very considerable quantity of blood continue to flow through it. In the Museum of University College there is an exceedingly interesting preparation that illustrates this point. It is one in which Sir Charles Bell ligatured the femoral artery for popliteal aneurism. The patient died a week after the operation, from erysipelas; on examination, it was found, and is shown by the preparation, that the femoral artery was double, and that, though only one portion of the vessel had been ligatured, the tumor, which continued to be supplied by the other branch, was completely consolidated. Hence it would appear that, if one half only of the influx of blood be arrested, obliteration of the sac by deposition of laminated fibrin may be expected to occur. After the aneurismal sac has been thus occluded, it progressively diminishes in size, and is at last converted into a small mass of fibroid tissue. The artery that has been ligatured becomes closed at two points—at the part designated (Fig. 453, *a*), and where it communicates with the sac (Fig. 453, *b*). In both these situations, it will be found to be converted into fibroid tissue; while between them there is an open space, through the medium of which the collateral circulation is freely carried on.

Porter, however, recommends that the ligature should be applied in such cases, though I cannot but doubt the propriety of this advice. When inflammation has been set up in the sac, with a tendency to suppuration of the tumor, it is a debatable question whether the ligature should be applied or not. In these cases I agree with Hodgson, that the artery should be tied; for even if the sac eventually suppurate, there will be less risk to the patient if this event occur after the application of the ligature, than if it happen while the artery leading into the tumor is pervious. If suppuration have already taken place around the sac, the application of the ligature above the inflamed tumor on the point of bursting would be worse than useless. In such cases, the line of practice must be determined by the seat of the aneurism. If this be in the axilla, groin, or neck, it should be laid freely open, the coagula scooped out, and the artery tied above and below the mouth of the sac—a most formidable and doubtful operation, but the only one that holds out a chance of success. If the aneurism be in the ham or calf, amputation would probably be the best course to pursue.

In some instances, there is no resource left to the Surgeon but to amputate. 1. Amputation must be performed when the aneurism is associated with carious bone or a diseased joint, as when a popliteal aneurism has produced destruction of the knee. 2. If the aneurism have attained so great a magnitude that it has already interfered seriously with the circulation through the limb, as indicated by considerable oedema, lividity, and coldness of the part, with distention of the superficial veins, it is a question whether the application of the ligature may not immediately induce gangrene, and whether the patient would not have the best chance of recovery by submitting to amputation at once; this is more particularly the case when the aneurism, whether previously large or small, has become diffused with impending gangrene, when removal of the limb must not be delayed. 3. If gangrene have actually supervened, and the patient's strength be sufficient to bear the operation, amputation should be done without delay. 4. If a diffused aneurism, whether suppurating or not, in the lower extremity, have been opened by mistake for an abscess, there is no resource left but immediate amputation.

The mortality after ligatures of the larger arteries for aneurism is very considerable. Thus, in 256 cases of ligature of the larger arteries for aneurism, collected and tabulated by Crisp, it would appear that the mortality amounted to about 22 per cent. And Porta finds that, among 600 cases of ligature of arteries for diseases and injuries of all kinds, the mortality amounted to 27 per cent. It must be borne in mind, that these are collections of reported cases, and that, if the unrecorded cases could be got at, the rate of death would, in all probability, be found to be much higher even than that above stated.

ACCIDENTS AFTER LIGATURE FOR ANEURISM.—The accidents that may follow the application of the ligature in a case of aneurism, are: 1, Secondary Hemorrhage from the seat of ligature; 2, the Continuance or the Return of Pulsation in the Sac; 3, the occurrence of Suppuration and Sloughing of the Tumor, with or without Hemorrhage from it; and 4, Gangrene of the Limb.

1. **Secondary Hemorrhage** from the seat of ligature presents nothing peculiar, and has already been discussed in vol. i. p. 404.

2. **The Continuance or Return of Pulsation** in an aneurismal sac after the ligation of the artery leading to it, is an interesting phenomenon, and one that deserves much attention. When the Hunterian operation is successfully performed, though the pulsation in the sac be entirely arrested, a certain quantity of blood continues to be conveyed into and through it by the anastomosing channels, and it is from this that the laminated fibrin is

and natural to the feel; if it be hard, incompressible, indicative of calcification; if it feel broader than natural; if a bruit be heard in it on applying the stethoscope; if, in fine, there be evidence of degeneration or dilatation of its coats, great caution should be used in attempting to ligature. Should the deligation of a diseased artery become unavoidable, the antiseptic catgut, or the ox-aorta ligature, would probably be the best material for the purpose. The ends being cut short, and the wound closed over them, the chance of sloughing and of unhealthy ulceration of the vessel would be greatly lessened.

It has occasionally, perhaps more frequently than the profession knows, happened to Surgeons that they have cut down upon an artery with the intention of tying it, and found it in so diseased a state that the application of the ligature was impracticable, and that it became necessary to close the wound without completing the operation. Liston and Aston Key have both had the candor to record such cases. In one case that happened to me in which it was thought necessary to tie the superficial femoral for popliteal aneurism, I found, on cutting down on the artery, that there was a small aneurismal dilatation just below the giving off of the profunda, and a tubular dilatation of the artery below this, rendering the application of ligature utterly impracticable. I afterwards tied the external iliac, but unsuccessfully. It must be remembered that, in such cases as these, not only are the arterial coats softened and incapable of bearing the strain of the ligature, but the vein is usually adherent, and consequently liable to perforation in passing the aneurism-needle between it and the artery. And even could the act of deligation be practised, secondary hemorrhage would undoubtedly occur at an early period in an artery that is incapable of healthy obliteration.

All operation should be avoided when there is any serious disease of the heart, and in cases of multiple aneurism where the second tumor is situated internally: but it has happened that two aneurisms in one limb, as of the popliteal and femoral arteries, have been cured by one ligature applied to the external iliac. Two aneurisms seated in corresponding parts of opposite limbs, affecting, for instance, the two popliteal arteries, may be successfully operated upon. But, if two aneurisms be seated on different parts of the body, as the axilla and groin for instance, at the same time, extensive disease of the arteries would be indicated, and it certainly would not be expedient to operate.

In certain cases, the Hunterian operation seldom succeeds. This happens in those instances in which it is necessary to apply the ligature very close to the sac, so as indeed rather to perform Anel's operation, as here there is the double danger of inflaming or wounding the sac, and of interfering with the collateral circulation of the limb. Those cases, also, in which the aneurism is very acute in its progress, increasing rapidly with forcible pulsation, having very fluid contents, and a large mouth to the sac, into which the blood is consequently driven at a full wave at each pulsation of the heart, are rarely favorable for the use of the ligature, inasmuch as stratification seldom occurs. When the aneurism is situated in the midst of loose and very yielding tissues, as in the axilla, where it readily expands to a large size, not being bound down by the surrounding parts, suppuration and sloughing of the sac are especially apt to occur after ligature. When it is diffused widely through the limb, with coldness and a tendency to incipient gangrene, the circulation of blood through the part is so much choked that deligation of the vessel will in all probability arrest it entirely, and thus produce mortification. When arteries can be felt to be calcified, it is a question whether they can be safely ligatured, as in all probability they will be cut or broken through by the noose, and the changes necessary for their occlusion will not take place.

certainly of more common occurrence after operations for carotid aneurism than for any other form of the disease. Thus, of 31 cases in which the carotid artery was tied for aneurism, I find that pulsation in the tumor continued or returned in 9 instances; whereas of 92 cases of inguinal aneurism, in which the external iliac artery was ligatured, the pulsation recurred in 6 cases only, and in several of these it is interesting to note that there were two aneurismal sacs in the same limb—one in the groin, the other in the ham; and that the pulsation, though permanently arrested in the popliteal, recurred in the inguinal aneurism. In the ham and axilla, pulsation occasionally though very rarely recurs. This difference in the frequency of the recurrence of pulsation in different aneurisms, is evidently owing to the different degrees of freedom of communication that exist between the sac and the collateral branches in various forms of the disease; thus in a carotid aneurism, the impulse of the heart may at once be brought to bear upon the contents of the sac, through the medium of the circle of Willis. But, in the case of inguinal, femoral, or popliteal aneurism, the anastomoses, consisting rather of the in-solutions of terminal branches than of open communications between large trunks, are less liable to transmit the blood in a pulsatory stream. For the same reason—the great freedom of the communication between the vessels of opposite sides—the pulsation has more frequently been found to continue uninterruptedly and distinctly, though reduced in force, after the ligature of the artery in carotid aneurisms, than in those in any other situation. The cases in which it returns after the cessation of a few hours only are perhaps as frequent in the groin and ham, as in the neck. In those instances in which the pulsation returns within the first twenty-four hours after the ligature, it usually ceases again in a few days, though it sometimes continues a week or two. When it recurs at a later period, it is apt to last somewhat longer. Compression antecedent to the ligature may so enlarge the collateral vessels as to favor a continuance or return of pulsation. I have once known the pulsation continue, though very much lessened, in a popliteal aneurism, after ligature of the superficial femoral, in a case in which treatment by compression had unavailingly been tried for nearly three months. In another case, in which I tied the external iliac artery for popliteal aneurism, owing to the superficial femoral being too diseased to admit of a ligature, the pulsation ceased completely for a time as I was tightening the ligature, but then returned, and became very marked in a few hours. In this case compression had been unavailingly employed before the artery was tied.

The *prognosis* of these cases is on the whole favorable, but few of them having eventually proved fatal. Of 26 patients in whom pulsation occurred, I find that three died; and in all of these the fatal result was occasioned by inflammation and sloughing of the sac. In all of the three instances, the pulsation recurred within the first twenty-four hours. When it returns at a more advanced period, there is little risk to the patient, as it is usually readily amenable to proper treatment.

A *Secondary Aneurism* is of extremely rare occurrence; indeed I believe there are only two unequivocal instances of this affection upon record, both of which took place in the ham; the original tumor having disappeared entirely after operation, the secondary disease made its appearance after a lapse of six months in one case, and in the other after four years. It is of importance to distinguish between a secondary aneurism and secondary or recurrent pulsation in an aneurismal sac. The term "*secondary aneurism*" should be restricted to those cases only in which an aneurismal tumor appears in the site of a former one, which has undergone consolidation and absorption. The question may be raised, whether aneurisms of this kind are in reality secondary or whether they may not originate in the dilatation of

deposited by which the consolidation of the tumor is ultimately effected. This stream of blood furnished by regurgitation, or by transmission through the smaller collateral channels, is continuous, and not pulsatory; occasionally, however, it is transmitted in sufficient quantity by some more than usually direct and open anastomosing branch, and thus gives rise to a continuance or to a return of the pulsation. It is interesting to observe that, in some of the cases in which this has happened, there has been a return of the bruit, but in the majority no sound appears to have been emitted.

The *period* of the return of the pulsation in the sac after the ligature of the artery varies greatly. In by far the majority of cases, at least two-thirds of those in which it has happened, a certain degree of thrill or of indistinct pulsation has been found in the sac shortly after the application of the ligature; at all events, within the first twenty-four hours. This may be looked upon as being rather a favorable sign than otherwise, as it is indicative of the free state of the collateral circulation, and generally soon disappears spontaneously, the sac undergoing consolidation. Next in order of frequency are those cases in which the pulsation returns in about a month or six weeks after the ligature of the artery, the collateral circulation having been fully established, and, after continuing for some length of time, gradually ceases. It more rarely happens that the pulsation returns between these two periods; that is to say, about ten days or a fortnight after the application of the ligature; though in some instances the slight vibratory thrill, scarcely amounting to a pulsation, which perhaps is perceptible a few hours after an artery has been tied, gradually strengthens at the end of a week or ten days into as distinct and forcible a beat as had been noticed before the operation. In some rare instances the pulsation has reappeared after the lapse of some months, the aneurismal tumor having in the meanwhile undergone absorption; then, indeed, it may with justice be looked upon as constituting a *secondary aneurism*, and as indicating a recurrence of the complaint.

The *cause* of the continuance or of the return of the pulsation in an aneurismal sac, must be looked for in too great a freedom of the collateral circulation. Indeed, it is an essential requisite for the manifestation of this phenomenon, that there should be so free and direct a communication between the artery on the proximal side of the ligature, and that portion of the vessel situated between the ligature and the sac, or the sac itself, as to enable the impulse of the heart to be transmitted in a pulsatory manner into the tumor. No regurgitant blood coming upwards from that portion of the artery which is distal to the sac, however free it may be, can communicate an impulse, as it never flows *per saltum* except in the special case of a continuous circle of large anastomoses, such as are met with between the arteries within the skull, or in the palmar and plantar arches. If any of the direct collateral or feeding vessels happen to be sufficiently large at the time of the operation to transmit the wave of blood, the pulsation in the sac will be continuous, or will return almost immediately after the application of the ligature. If they be at first too small for this, they may become enlarged as part of the anastomosing circulation, and then the pulsation will return as soon as their calibre is sufficient to transmit the heart's impulse. Besides these conditions in the size and distribution of the vessels of the part, it is not improbable, as has been supposed by Porter, that certain states of the blood in some individuals may, from causes with which we are unacquainted, render it less liable to coagulate than usual, and thus dispose to a return of the pulsation in the sac, which remains filled with fluid blood.

The phenomenon under consideration has been noticed in all parts of the body after the performance of the Hunterian operation, though it occurs with different degrees of frequency after the ligature of different arteries, and is

certainly of more common occurrence after operations for carotid aneurism than for any other form of the disease. Thus, of 31 cases in which the carotid artery was tied for aneurism, I find that pulsation in the tumor continued or returned in 9 instances; whereas of 92 cases of inguinal aneurism, in which the external iliac artery was ligatured, the pulsation recurred in 6 cases only, and in several of these it is interesting to note that there were two aneurismal sacs in the same limb—one in the groin, the other in the ham; and that the pulsation, though permanently arrested in the popliteal, recurred in the inguinal aneurism. In the ham and axilla, pulsation occasionally though very rarely recurs. This difference in the frequency of the recurrence of pulsation in different aneurisms, is evidently owing to the different degrees of freedom of communication that exist between the sac and the collateral branches in various forms of the disease; thus in a carotid aneurism, the impulse of the heart may at once be brought to bear upon the contents of the sac, through the medium of the circle of Willis. But, in the case of inguinal, femoral, or popliteal aneurism, the anastomoses, consisting rather of the communications of terminal branches than of open communications between large trunks, are less liable to transmit the blood in a pulsatory stream. For the same reason—the great freedom of the communication between the vessels of opposite sides—the pulsation has more frequently been found to continue uninterruptedly and distinctly, though reduced in force, after the ligature of the artery in carotid aneurisms, than in those in any other situation. The cases in which it returns after the cessation of a few hours only are perhaps as frequent in the groin and ham, as in the neck. In those instances in which the pulsation returns within the first twenty-four hours after the ligature, it usually ceases again in a few days, though it sometimes continues a week or two. When it recurs at a later period, it is apt to last somewhat longer. Compression antecedent to the ligature may so enlarge the collateral vessels as to favor a continuance or return of pulsation. I have once known the pulsation continue, though very much lessened, in a popliteal aneurism, after ligature of the superficial femoral, in a case in which treatment by compression had unavailingly been tried for nearly three months. In another case in which I tied the external iliac artery for popliteal aneurism, owing to the superficial femoral being too diseased to admit of a ligature, the pulsation ceased completely for a time as I was tightening the ligature, but then returned, and became very marked in a few hours. In this case compression had been unavailingly employed before the artery was tied.

The prognosis of these cases is on the whole favorable, but few of them have eventually proved fatal. Of 26 patients in whom pulsation occurred, I find that three died; and in all of these the fatal result was occasioned by inflammation and sloughing of the sac. In all of the three instances, the pulsation recurred within the first twenty-four hours. When it returns at a more advanced period, there is little risk to the patient, as it is usually amenable to proper treatment.

A Secondary Aneurism is of extremely rare occurrence; indeed I believe there are only two unequivocal instances of this affection upon record, both of which took place in the ham: the original tumor having disappeared entirely after operation, the secondary disease made its appearance after a space of six months in one case, and in the other after four years. It is of importance to distinguish between a secondary aneurism and secondary or recurrent pulsation in an aneurismal sac. The term "*secondary aneurism*" should be restricted to those cases only in which an aneurismal tumor appears in the site of a former one, which has undergone consolidation and absorption. The question may be raised, whether aneurisms of this kind are really secondary or whether they may not originate in the dilatation of

a portion of the artery contiguous to the seat of a former disease. It is certainly not very easy to understand how an aneurismal sac that has once undergone consolidation and absorption can again become dilated into a pulsating tumor; and I think it most probable that, although the conservative aneurism may be found in the same surgical region as the primary one, it in reality takes its origin from a slightly higher part of the artery, where the same structural change may have been in progress that determined the disease in the first instance at a lower point. Double aneurism thus arising is, indeed, occasionally met with in the ham as a primary disease. I have seen a case in which an aneurismal tumor was situated in the ham, and another at or immediately above the aperture in the adductor muscle: if the artery in such a case as this had been tied before the second tumor had attained any magnitude, we can easily understand how, when this became dilated, it might have been considered to be a new enlargement of the original sac, whereas, in reality, it was nothing more than a new aneurism forming in the close vicinity of the old one.

Enlargement of an aneurismal sac without pulsation, after the ligature of the artery leading to it, is an interesting phenomenon, and one that might cause the true nature of the tumor to be misunderstood, as it closely resembles in its slow and gradual increase the growth of a malignant tumor. It is occasioned by the distention of the sac by regurgitant blood brought into it through the distal end of the vessel, without sufficient force to cause pulsation, though with sufficient pressure to occasion a gradual increase in the size of the swelling.

Treatment of Recurrent Pulsation.—In by far the majority of cases of secondary pulsation, this phenomenon ceases of itself in the course of a few days or weeks from consolidation of the sac, in the same way as after ligature of the artery, by the deposition of lamellated fibrin. This tendency to consolidation of the tumor may be much assisted by means calculated to lessen the force of the impulse of the blood into the sac, such as compression of the artery above the point ligatured, rest, the elevated position, and the cautious application of cold to the part; cold, however, must be carefully applied, lest, the vitality of the limb being diminished, gangrene be induced. At the same time, direct pressure may be exercised upon the sac, so as to moderate the flow of blood into it; this has in many cases succeeded in procuring consolidation of the tumor, and may most conveniently be applied by means of a compress and narrow roller. This plan is especially adapted to popliteal and inguinal aneurisms, but cannot so well be exercised upon those situated in the neck. Care must be taken that the pressure be not at first too powerful, lest gangrene result; the object is not so much to force out the contents of the tumor, or to efface this, as simply to restrain and moderate somewhat the flow of blood into it. Should the aneurism be so situated that pressure can be exercised upon the artery above the point ligatured, this should be had recourse to either by the finger or by instrument, and will be both safer and more likely to be effectual than direct pressure. I succeeded in this way in curing a very remarkable case of recurrent pulsation in a popliteal aneurism. The patient, a man about thirty-five years of age, was admitted into University College Hospital for an aneurism, about the size of an orange, in the right ham. Treatment by compression was employed, without any effect being produced in the tumor for three months. During this period compression was employed in all forms—by Cartie's instrument, the weight, the finger, and flexion. I then ligatured the superficial femoral artery in Scarpa's triangle. The pulsation was arrested in the tumor when the ligature was tied, but returned in a slight degree in about an hour, and slowly increased, never becoming at all forcible, but being very distinct.

The ligature separated on the fourteenth day. The limb was bandaged, and a pad applied over the aneurism without any effect; and the limb was raised, but still the pulsation continued. Carte's compressor was again applied to the common femoral artery, and used for about three hours in an intermittent manner, when the pulsation finally ceased.

In the event of the pulsation not disappearing under the influence of pressure, conjoined with rest, dietetic means, and the local application of cold, there are three courses open to the Surgeon: 1, To ligature the vessel higher up; 2, to perform the old operation of opening the sac; and, 3, to amputate, if the aneurism be situated in a limb.

With regard to ligaturing the artery at a higher point, I am not acquainted with any cases that throw much light on the probable success of such an operation. We know that the ligature of an artery high up for secondary hemorrhage, after previous deligation of it, is a most disastrous procedure. But here the conditions are by no means identical with, or even similar to, those that accompany recurrent pulsation. In the case of secondary hemorrhage, there has usually not been time for the full development of the collateral circulation; whereas, in the case of recurrent pulsation, many weeks would probably have elapsed before the second operation would become necessary, so that ample time would be given for the enlargement of the anastomoses; and, besides this, the very occurrence of the return of pulsation may be taken as evidence of an unusually free anastomosing circulation. I think, therefore, that if such a case were by any possibility to occur, in which recurrent pulsation could not be checked by the application of pressure, digital or instrumental, to the artery above the point originally ligatured, aided by the other appropriate local and constitutional means that have been mentioned above, the Surgeon would adopt the proper course by ligaturing the artery higher up—*ex. gr.*, the common femoral or external iliac, if the superficial femoral had been the one previously tied. In the event of this not being thought advisable, he must choose between one or other of the two remaining operations, viz., amputation, or opening the sac. Of these measures, I should certainly prefer amputation, as offering the most favorable chance to the patient. The operation of opening the sac, turning out its contents, and ligaturing the vessel supplying it, is in any circumstances a procedure fraught with the greatest danger to the patient, and full of difficulty to the Surgeon, even when he knows in what situation to seek the feeding vessel. How much greater then must the difficulty be, when he is in uncertainty as to the point at which the artery enters the sac, and cannot know whether there be more than one arterial branch leading into it. In the event, therefore, of all other means failing, and of the pulsation in the tumor continuing, amputation is the only resource left to the Surgeon.

In those situations in which this is impossible, the Surgeon may occasionally attempt the old operation. Smythe, of New Orleans, as a last resource, laid open a subclavian aneurism, for which he had successfully tied the innominate some years before, but failed to secure the artery, and the patient died. Morris, however, has successfully adopted this proceeding in a case of carotid aneurism after ligature of the common trunk had failed; and Berkeley Hill in a case of axillary aneurism after ligature of the subclavian.

Since the introduction of absorbable ligatures into surgical practice, a return of pulsation has in a few cases been due to a restoration of the lumen of the artery after the disappearance of the ligature. This is recognized by the presence of pulsation in the vessel at the point at which it was tied. These cases belong to a different class to those in which the vessel has been permanently occluded, and require different treatment. The artery may be

ligatured again at or near the same spot or at some other point. In a case of this kind that occurred under the care of Christopher Heath in University College Hospital, the femoral was successfully tied in Hunter's canal after ligature of the artery in Scarpa's triangle had failed. The causes of failure of the ligature have already been described (vol. i. p. 421).

3. Suppuration and Sloughing of the Sac.—When, after the ligature of its supplying artery, an aneurism is about to suppurate, instead of diminishing in size, it increases, with heat, pain, pulsation, and some inflammatory discoloration of the skin covering it. This gradually becomes thinned, and at last gives way; the contents of the tumor, softened and broken down by inflammation and the admixture of pus, are discharged through the aperture in its wall, in the form of a dark purplish-brown or plum-colored and often fetid fluid, intermixed with masses of a soft dark coagula, or of the drier laminated fibrin, which may not inaptly be compared in appearance to portions of raisins or dates. The escape of these matters, variously altered, may be accompanied or followed by the escape of florid arterial blood. This hemorrhage, which is the great source of danger in the suppuration of an aneurismal sac, may occur in a sudden violent gush, by which the patient may at once be destroyed, at the time of the rupture of the tumor, or it may continue in small quantities, which, after ceasing, recur from time to time, thus gradually exhausting the patient. It is this occurrence of secondary hemorrhage that constitutes the principal danger after suppuration of aneurism, which otherwise is not a source of any very serious risk to the patient; about one-fourth only of the cases in which the sac has suppurated having had a fatal termination, and almost all those in which death resulted having proved fatal by hemorrhage. The patients in a few remaining instances have been carried off by some special accidents, such as the pressure of the sac on the pharynx or œsophagus, or the discharge of the contents of the tumor into the pleura or bronchial tubes. Hemorrhage is more liable to occur when suppuration takes place a few weeks after the ligature of the artery, than when a longer interval has elapsed. That hemorrhage does not happen more frequently after suppuration of the sac is very remarkable, and must be owing either to the sealing by adhesion or plugging by coagulum of the mouth of the aneurism, where it communicates with the interior of the artery. It is owing to this plugging, also, that in many cases the fatal bleeding does not occur at the moment of rupture, but only after a lapse of some days, or even weeks, and then most usually under the influence of some incautious movement of the patient, by which the coagulum or adhesion is suddenly disturbed. Those cases are most dangerous in which pulsation has returned in the sac after the ligature of the vessel, but before the supervention of suppuration; as in these the tumor is so freely supplied with blood that, if it burst, fatal hemorrhage will with certainty supervene.

This accident is much more frequent in some situations than in others, and is more liable to occur in aneurisms of the axilla or groin, than in those of the arm or of the neck. The proximity of the ligature and the necessary interference with the sac in its application, especially in large axillary or inguinal aneurisms, is undoubtedly a frequent cause of it. The large size these tumors rapidly attain, in consequence of the laxity of their areolar connections, also favors it. Until recently it was believed that the occurrence of simple coagulation, instead of gradual deposit of laminated fibrin, was an important factor in the production of suppuration of the sac; but our late experience of the treatment of aneurism by rapid compression clearly shows that the danger has been greatly exaggerated. In other cases it would appear that the fibrin, though properly deposited, acts as a foreign body, and gives rise to inflammation and suppuration in the wall of the sac and the sur-

rounding areolar tissue. Besides this, it has been very justly remarked by Porter, that the excessive handling and frequent examination to which an aneurismal tumor occurring in a hospital patient is usually subjected, may induce inflammation and give rise to suppuration.

The period at which suppuration of the sac may occur after the ligature, varies from a few days to as many months. In the majority of instances, it would appear to take place between the third and eighth weeks; later than this it seldom happens, though it may do so after the lapse of several months, as in a case recorded by Sir A. Cooper, in which a carotid aneurism suppurated at the eighth month.

Treatment.—When an aneurism is suppurating, and is on the point of giving way, it will be better to make an incision into it with antiseptic precautions, so as to let out the broken-down contents at once. It must then be treated like an ordinary abscess, with a view to its filling up by granulation which, however, will necessarily be a slow process, in consequence of the great size and depth of the opening. During the whole of this time a *tournequet* should be kept loosely applied upon the artery above the sac, so as to be tightened at any moment if bleeding take place. If hemorrhage have already supervened, the case is attended with immediate danger. In such a case as this, the first indication is clearly to arrest the flow of blood, so as to prevent the patient from dying at once. This can best be accomplished by turning out the coagula and plugging the sac with lint or compressed sponge, retained *in situ* by a firm graduated compress, and well-applied roller. The hemorrhage having thus been arrested for a time, the surgeon should take into consideration what steps should be adopted permanently to restrain it. In some cases, indeed, though these are exceptional, the plug and compress may be sufficient to prevent a recurrence of the bleeding; but in general it will not do to trust to these means, unless the anatomical relations of the part be such as to preclude the possibility of adopting any more active measures.

Various plans suggest themselves to the Surgeon for the permanent suppression of the bleeding. The sac may be laid open, and an attempt made to ligature that portion of the artery from which the blood issues. But this can scarcely be expected to succeed, as, in the majority of the cases, the coats of the vessel being softened and pulpy, there would be little prospect of its holding a ligature, even if it were possible to expose it before the patient perished of hemorrhage. Indeed, though this plan has been several times tried, I am not aware that by it the Surgeon has ever succeeded in arresting the bleeding from a suppurating aneurismal sac.

The application of the actual cautery to the bleeding orifice would, I think, hold out a better chance, more particularly if the blood were poured out from a collateral vessel of a small size. In this way, Morrison, of Monte Video, succeeded in arresting the bleeding of an aneurism in the groin that had suppurated. Should this means, however, not suffice (and it is the only means that can be applied in many situations, as in the groin and axilla), there is no course left but, in those situations in which it can be done, either to ligature the artery higher up or to amputate. The application of a ligature nearer the centre of the circulation, even though practicable, appears to me to be of very doubtful utility; for the probability is, that the circulation through the limb, embarrassed as it must have been by the first ligature, and by the subsequent distention and suppuration of the sac, will be so much interfered with when the artery is tied a second time, that gangrene will result, or else that the collateral circulation, if sufficiently active to maintain the vitality of the limb, will also keep up the hemorrhage from the opening in the artery communicating with the sac. In these circumstances, the only

course left to the Surgeon is amputation of the limb when the aneurism is so situated that it can in this way be removed.

4. Gangrene of the Limb.—The general subject of gangrene of a limb, following injury and ligature of the main artery, has already been described (vol. i. p. 443); and we have at present to consider only those cases in which it occurs after the operation for aneurism.

Causes.—If the aneurismal sac have attained a large size with great rapidity, it may, by its pressure on the collateral vessels, or on the veins in its vicinity (Fig. 454), produce such an amount of disturbance in the circulation of the limb, preventing the influx of arterial or obstructing the efflux of venous blood, as to occasion a great liability to the occurrence of gangrene. But perhaps the principal source of danger consists in the aneurism becoming suddenly and widely diffused, more particularly in those cases in which the anatomical relations of the collateral vessels are such, as in the ham, that they may readily and uniformly become compressed by the effused blood. In these cases the additional embarrassment induced in the circulation of the limb by the ligature of its main artery will readily induce gangrene; and hence it is that, in diffuse aneurism of the lower extremity, ligature of the artery is so commonly followed by mortification.

Fig. 454. — Popliteal Aneurism compressing the Vein, and thus causing Gangrene of the Limb: a, Artery; b, Vein compressed at d; c, Aneurism.

Loss of blood, either in consequence of secondary hemorrhage, or in any other way before or after the application of the ligature, is very apt to be followed by gangrene; the more so, if it have been necessary to apply a ligature to a higher point on the trunk of the vessel than had previously been tied. This secondary ligature of a large artery in cases of aneurism has, I believe, been invariably followed by gangrene of the limb, when done in the lower extremity; the interference with the collateral circulation by the second ligature being so great, that the vitality of the part cannot be maintained.

Besides these causes, the occurrence of *erysipelas*, exposure of the limb to cold, or to an undue degree of heat, or subjecting it to the compression of a bandage, may be attended by consequences fatal to its vitality.

The period of *suppuration* of gangrene of the limb is usually from the third to the tenth day; it seldom occurs before this period, unless incipient mortification have already set in before the artery was tied. Gangrene usually follows the ligature of the external iliac at an earlier period than that of any other artery. In cases of aneurism, the gangrene is always of the dark and moist variety, owing to its being commonly dependent on pressure upon the large venous trunks by the aneurismal tumor.

Treatment.—The general preventive treatment of gangrene following the ligature of the artery for aneurism must be conducted on the same principles as when it arises after ligature of arteries generally (vol. i. p. 443). But some special modifications of it are required, so far as the aneurism is concerned. When the gangrene occurs from the pressure of the sac upon the accompanying vein, it has been proposed to lay the tumor open, and to turn out its contents, thus removing the compression exercised by it. The danger of such a proceeding consists in the probability of the occurrence of hemor-

charge from the opening made into the sac, and in the risk attending suppuration set up in the sac; yet it would appear that, in two cases in which this practice has been adopted, no bad results followed. Thus, Lawrence has related a case of diffused aneurism of the popliteal artery, in which this plan was had recourse to with the best results; and Benza has recorded a case of popliteal aneurism in which the same practice was adopted in consequence of great oedema and incipient gangrene of the foot; after the extraction of a quantity of flesh-like fibrin from the sac, the patient made an excellent recovery. These cases would certainly justify the Surgeon in adopting such a course when the danger of gangrene is imminent, and dependent on the size and pressure of the tumor. Should, however, the gangrene show any disposition to extend, or should there be hemorrhage from the sac after it has been laid open, the Surgeon must hold himself in readiness to amputate without delay. When gangrene has once fairly set in, there is no reasonable prospect of saving the limb; and the sooner amputation is done the better. The limb must always be removed high up above the sac, and if possible, not only at some distance from the parts that have mortified, but also above the part to which the serous infiltration that precedes mortification has extended. The upper extremity must generally be removed at the shoulder-joint, the lower above the middle of the thigh. In these cases there will generally be a considerable amount of hemorrhage, and many vessels will require to be tied in the stump, in consequence of the enlargement of the collateral circulation.

COMPRESSION BY INSTRUMENTS.—In consequence of the dangers and difficulties attendant upon the use of the ligature, Surgeons have endeavored to treat aneurism by compression. The employment of direct pressure on the aneurism was almost naturally suggested as a means to counteract the extension of the disease by the pressure of the blood from within, and has consequently been applied from a very early period in the treatment of the affection. This plan of treatment was first employed by Bourdelot at the close of the seventeenth century; afterwards by Gengn, Heister, Guattani, and others. These Surgeons made the pressure directly upon the sac; and Guattani and Flajani relate several cures that they effected in this way; but the method was so uncertain in its results, and so dangerous, from irritating and inflaming the sac, that it fell into disuse. The French Surgeons introduced a modification of the pressure plan, by laying open the sac, clearing out its contents, and applying the pressure directly over the opening into the vessel. Deschamps exposed the artery leading to the sac, and compressed this with an instrument which he termed the "presse-artere." These barbarous modes of treatment, however, were entirely set aside by the safety and comparative success of the Hunterian operation; and compression in aneurism was rarely practised by Surgeons after the great step made by John Hunter in the treatment of this disease. Yet we find that John Hunter himself, Blizard, and Freer attempted, though without success, to cure this disease by pressure on the artery leading to the sac. Pelletan and Duboue appear to have been the first who successfully applied pressure to the artery above the sac instead of to the aneurism itself; this was in 1810. After this period, various attempts were made methodically to treat aneurisms in this way, but the merit of having introduced the practice of compression in the treatment of aneurism into modern surgery, of having given it a definite place in our art, and of having established the true principles by which it acts, unquestionably belongs to the Dublin Surgeons; amongst whom the names of Hutton, Bellingham, Tufnell, and Carte deserve especial mention.

Principle of Compression.—In the early trials of the cure of aneurism by compressing the artery on the cardiac side of the tumor, the Surgeons

who employed this method acted on an erroneous theory; and, the principle not being understood, the practice was bad. It was supposed that it was necessary, in order that a cure might take place, that the *whole* flow of blood through the artery should be arrested; that inflammation of the vessel at the point compressed should be set up; and that the consolidation of the aneurism depended upon the obstruction of the vessel consequent upon the inflammation. This led to the employment of such violent and forcible compression, with the view of exciting inflammation in the artery, that the patient could seldom bear it for a sufficient length of time to effect a cure, sloughing of the skin commonly resulting from the severity of the pressure to which it was subjected. To the Dublin Surgeons belongs the very great merit not only of having pointed out the error of this doctrine, but having distinctly laid down as the principle of the practice, that, in the majority of cases, the aneurism was cured, when the artery leading to it was compressed, in precisely the same way as when a spontaneous cure takes place, or when the Hunterian operation is performed—viz., by the deposit of stratified fibrin in the sac, and by the consequent consolidation of this (Fig 455), aided by the contraction of the walls of the sac; and that, as in the case of

Fig. 455. Sac of Aneurism cured by compression. Deposit of laminated Fibrin.

ligature of the vessel, it was not necessary that the whole of the circulation through the artery should be entirely and permanently arrested, but merely that it should be lessened in quantity and force to such an extent as to be compatible with the deposition of laminated fibrin in the sac, and it was clearly shown by examination after death that, if the pressure were properly conducted, the artery was in no way injured or occluded at the part compressed. The recognition of the true principles on which compression of the artery leading to the sac cures the aneurism, has led to important results; for as the severe pressure that was formerly considered necessary is now known not only to be unnecessary, but often to be absolutely injurious, no amount of compression is exercised beyond what is requisite to restrain and moderate the flow of blood into the sac; no attempt being made to compress the artery so severely as to lead to its obliteration by inflammation.

But, although, where the pressure is moderate or the anastomosing circulation free, the consolidation of the contents of the sac takes place in the way that has just been described, it would be an error to suppose that this is the process by which the aneurism becomes cured in all cases in which recourse is had to compression. There can be no doubt that in some cases, where consolidation has taken place in a few hours after the employment of pressure, coagulation of the contents of the sac has suddenly occurred, and this sudden coagulation, which at one time was dreaded by surgeons, has been found by increased experience to be in the highest degree advantageous, as leading to a more rapid and equally certain cure of the aneurism.

In the tubular form of aneurism, which is far less frequent than the sacculated in the extremities, the cure appears to take place, if it occurs at all, rather by the gradual contraction of the partially emptied sac than either by the slow deposit of laminated fibrin, or by the rapid and almost sudden coagulation of its contents. The sac gradually shrinks, and shreds of fibrin only are found adherent to its sides. But although I believe that the consolidation of the aneurism, whether sacculated or tubular, has a considerable influence upon the mode in which compression acts in effecting a cure, and also upon the time that is occupied in the treatment, this being much shorter

in the sacculated than in the tubular form of the disease; yet there can be no doubt that this is materially influenced also by two other circumstances—viz., the condition of the blood within the sac, and the completeness of the compression.

When the sac is filled with fluid blood, and the compression is not uninterrupted complete, the sac appears to empty itself to a considerable extent, and eventually to consolidate by the deposit of laminated fibrin. But, if the sac already contain some solidified layers, and the compression be continuous and complete, the coagulation of the remaining fluid part of its blood is apt to take place rather suddenly. But in all cases the contraction of the sac, consequent upon the arrest or restraint of the current of blood into it, is an important element in the cure. Illustrative of this mode of cure, there is a preparation in the Museum of University College (Fig. 456).

From all this, then, it would appear that the consolidation and cure of an aneurism by compression may take place in three different ways: 1, by the slow deposit of laminated fibrin; 2, by rapid coagulation of the contents of the sac; 3, by contraction of the sac. The particular mode of cure will depend upon the completeness of the compression and the more or less perfect arrest of the blood in the sac, the coagulability of that blood, and the shape of the aneurism.

Circumstances Influencing Success.—The success of the treatment by compression depends greatly upon a scrupulous attention to a number of minor circumstances which, though each be trifling in itself, become of importance when taken as a whole. During the whole of the treatment, also, the patient's general health should be attended to in accordance with those dietetic and medical principles that have already been laid down in speaking of the constitutional treatment of the disease. The irritability of the heart must also be subdued, and the irritation of the system lessened, by the use of opiates or of chloral; and the patient should be put into a comfortable bed, with firm and well-secured pillows and mattresses, so that his position may not be changed. As it is principally in aneurism of the lower extremity that compression can be employed, we shall proceed to describe the method of its application here.

Application of the Compressor.—The thigh should, if necessary, be shaved, and the skin should then be powdered, and the limb bandaged with a soft roller; a pad being laid on the tumor. Pillows must also be comfortably arranged under it, the knee being semiflexed. Much of the success of the treatment will depend upon the kind of instrument used. The ordinary horseshoe, or Signorini's tourniquet, was the one first employed, and this will, in many cases, answer the purpose perfectly well; but as it is somewhat difficult to regulate the pressure with this instrument, and as it is not unfrequently exercised too powerfully, it has generally given place at the present day to the very ingenious apparatus of Carte which, as it substitutes an elastic force derived from vulcanized India-rubber bands for the unyielding pressure of the screw, accommodates itself better to the flesh and is less likely to produce injurious compression. This instrument, as well as the other contrivances which have at various times been invented for the treatment of aneurism by compression, are described by Bellingham

Fig. 456.—Sac of Tubular Aneurism cured by Compression, Contraction of Sac, and Irregular Deposit of Fibrin.

and Tuffnell, in their works on this subject, to which I must refer for a fuller account than I can here give.

In applying the compressor, especial care must be taken that it is well padded in every part, so as not to gall the skin. In some of the early cases in which I saw compression employed in London by means of the horse-shoe tourniquet, much inconvenience resulted from want of attention to this particular. The tendency to fretting of the skin is much lessened by powdering the limb; and the removal of the hairs by shaving diminishes materially

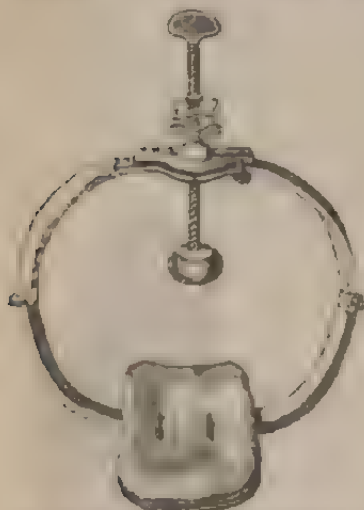

Fig. 457. Compressor for the Middle of the Thigh.

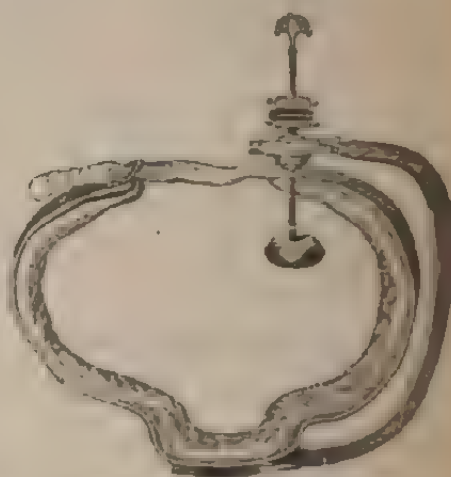

Fig. 458. Compressor for the Groin.

the irritation produced by the instrument. In order to keep up continuous pressure, and at the same time to prevent any one part of the skin from being injuriously galled, it is of very great consequence that two instruments should be used at the same time, so that when one is screwed down the other

may be loose; these instruments need not be placed closely together. If the aneurism be in the ham, it will be sufficient for one (Fig. 458) to be applied to the groin, whilst the other (Fig. 457) is put upon the middle of the thigh (Fig. 459). In using the instrument, the great point, as Tuffnell most properly remarks, is to control the circulation with the minimum of pressure. In order to do this, the first instrument should be screwed down so that all pulsation ceases in the tumor, but still not so tightly as completely to arrest all the flow

Fig. 459.—Two Compressors applied for Femoro-popliteal Aneurism.

of blood through it. As the pressure exercised by this becomes painful, the second one must be screwed tight, and then the first compressor may be

darkened. In this way an alternation of pressure can be kept up without much pain or inconvenience. If possible, the patient should be taught how to manage the instrument himself, and will often find occupation and amusement in doing so. If, however, it excites much pain or irritation, as it does in some subjects, it may be necessary to give opiates or chloral hydrate. The pressure should, if possible, be continued during sleep; but if it prevent the patient from taking his natural rest, the suggestion made by Tuffnell, of unscrewing the instrument slightly, and, when the patient is asleep, gently tightening it again without awakening him, may advantageously be adopted. It is indeed surprising how very little unscrewing will relieve the pain of the compression. A large cradle should be placed over the patient's body, so that the weight of the bed-clothes may be taken off the apparatus, and that the patient may manage it without risk of disturbance. Should there still be much uneasiness, the instrument might be taken off for a few hours, and compression kept up in an intermittent manner. Even in such circumstances as these, consolidation of the sac may ensue.

In some cases, in which, from the situation of the aneurism, deep and severe pressure is required to control the circulation, the pain becomes so unendurable that the patient cannot submit to the treatment sufficiently long for a good effect to be produced. In such cases opium or chloral hydrate may be given with advantage, so as to enable the patient to bear the pressure. But in some instances more complete narcotism is necessary for him to endure it. In these circumstances, chloroform becomes a most useful adjunct; and by maintaining the anaesthesia for several hours, the amount and duration of pressure requisite to effect a rapid cure may be maintained. In this way W. Murray, of Newcastle-on-Tyne—to whom is due the merit of employing prolonged anaesthesia as an adjunct to compression—cured an aneurism of the abdominal aorta by keeping up pressure on that vessel for five hours under chloroform. Heath, of the same town, cured an aneurism of the external iliac by compressing the abdominal aorta for seven hours under chloroform. Mayoth, of Dublin, treated an ilio-femoral aneurism successfully by compressing the common iliac artery for four and a half hours; and Lawson treated an inguinal aneurism successfully by pressure on the abdominal aorta for four hours. In two cases of popliteal aneurism I kept up completely obstructing pressure on the common femoral artery, under chloroform, for twelve hours. By these means the only serious objection to the employment of pressure, and the most common cause of its failure, may be prevented; and it is clear that, under chloroform, pressure may be applied to arteries, such as the subclavian and carotid, in which it could not otherwise be used. The employment of a weight may sometimes be advantageously substituted for the clamp, and often occasions less distress to the patient. For this purpose the apparatus (Fig. 460) will be found very useful.

Fig. 460. P. H. Watson's Weight Compressor. The circular dotted line shows the position of the limb.

A very simple compressor is Tuffnell's, represented in Figs. 461, 462. It consists of little more than a tross spring, with a pad to compress the artery, and straps to fix it in its place, and increase, by being tightened, the force of the compression.

The Effects upon the tumor vary considerably. In some cases it rapidly and suddenly solidifies; more commonly, however, this is a gradual process.

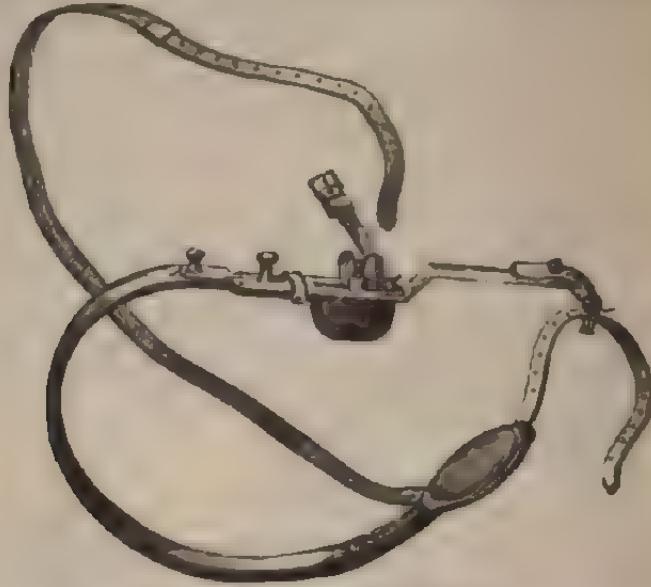

Fig. 461.—Tuffnell's Compressor.

the aneurism becoming more painful and solid, with less pulsation and bruit. As the solidification takes place, there is usually some restlessness, a feeling

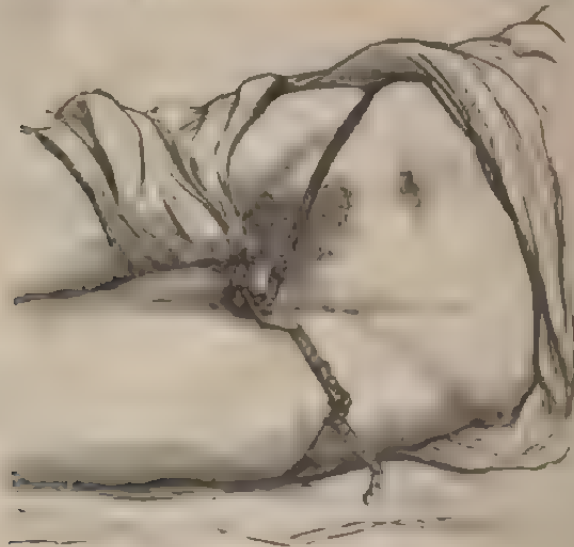

Fig. 462 — Tuffnell's Compressor Applied.

of general uneasiness, and of constitutional disturbance, which is best quieted by opiates. As the pressure is continued, and the tumor begins to

harden, the anastomosing vessels enlarge, with a good deal of burning pain in the limb generally, and arterial pulsations in situations where usually none are felt. The abnormal pulsation, in these cases, is always found to occur in much the same situations, the same vessels appearing to undergo distention. Thus Tutnell has made a remark, which I have had more than one opportunity of verifying, that, in the treatment of popliteal aneurism by compression, three arteries will be found to be enlarged, one of which passes over the centre of the tumor, another over the head of the fibula, and the third along the inner edge of the patella: he states also that the severe burning pain which is felt in these cases is owing to the artery accompanying the communicating peronei nerve being enlarged. After complete solidification of the tumor has taken place, the compression ought to be continued for at least forty-eight hours, so as to secure against the occurrence of a relapse.

The **Duration of the Treatment** varies very greatly. In some cases, as above stated, the tumor has become solidified in a few hours, or in two or three days. In other instances, the treatment has required to be protracted for more than three months before a cure has resulted. Of 26 cases of femoral or popliteal aneurism cured by compression in the London hospitals, the average time, according to Hutchinson, was nineteen days. Barwell has collected from American, British, and Continental journals all the recorded cases of popliteal aneurism cured by compression in the ten years 1870 to 1879 inclusive, and he gives the following statistics of the duration of the treatment. For instrumental compression the longest period was 7 weeks, the shortest 24 hours, the mean of 19 cases in which the time was recorded, 12 days; for digital compression, the longest period was 21 days, the shortest 4½ hours, and the mean of 13 cases 5½ days; for combined instrumental and digital compression the longest period was six months, the shortest 44 hours, and the mean of 12 cases 44½ days. Much, of course, will depend, in this respect, on the constitution of the patient, and on the condition of the tumor; those circumstances which are most favorable to the spontaneous cure of the aneurism will also influence the rapidity of the cure by compression. There are, undoubtedly, certain conditions of the blood in which it is little disposed to coagulate, and in these cases the duration of the treatment will necessarily be prolonged. So also, when the aneurism is tubular, we must expect that the blood which passes freely through it in the direct current of the circulation will be slower in undergoing those changes that lead to its coagulation than when the disease is sacculated, and thus contains a retention of blood that is not so directly influenced by the current through the sac. In the early days of the compression-treatment there was an indisposition on the part of Surgeons to apply it very effectually and firmly, and a longer time was expended over it than is now generally the case; and the example set by Murray, with regard to abdominal aneurism, has been followed with success in respect to the femoral, popliteal, and other forms of the disease, the compressor being screwed down tight on the artery so as completely to arrest for the time all circulation through the sac, the patient kept under chloroform, and the cure effected in a few hours.

Applicability.—Of the great value of compression in the treatment of aneurism, there can be no doubt; more especially when the tumor is situated in the arteries of the lower extremity below the middle of the thigh. In aneurism occurring in the vicinity of the trunk, as in the iliac, the carotid, subclavian, and axillary arteries, it is generally not so applicable; although, as we have already seen, aneurisms in the groin have been cured by compression of the abdominal aorta, or of the iliac artery. Spontaneous aneurism is extremely rare in the upper extremity; and, as the traumatic forms of the disease which occur here generally require that the sac should be laid open,

it is seldom found necessary to have recourse to it in this part of the body, though it may be and has been successfully applied to the brachial artery.

The great question with regard to compression appears, after all, to be whether it possesses any special advantages over the ligature, in the treatment of those aneurisms in which its employment is practicable. The principal objections that have been urged against compression are, that its employment is more painful and tedious than the use of the ligature; and that those cases that are unpromising to the ligature, or that require amputation rather than deligation of the artery, are equally unfavorable to compression, and cannot be saved by its employment.

To these objections it may with justice be answered that the pain attendant on the employment of compression depends very greatly upon the skill and care with which the apparatus is applied and managed throughout, as well as upon the kind of instrument used, being certainly much diminished when Carte's elastic compressor is employed; and that, as has already been shown, the pain may be overcome by the use of anesthetics. With regard to the relative tediousness of the treatment under the two plans, it would appear that in reality there is but little difference; for although some cases, in which compression is used, are prolonged over a considerable space of time, yet they do not occupy more than is often consumed when accidents of various kinds follow the use of the ligature; and it not unfrequently happens in compression, but can never occur after the employment of the ligature, that the patient is cured of his disease in a few hours or days. Taking, however, the averages, we find that in the Dublin cases the treatment lasted twenty five days, and in the London cases collected by Hutchinson but nineteen, and this is not very different to what formerly happened when silk ligatures were applied so as to cut through the artery and be finally withdrawn from the wound: for of fifty-four cases recorded by Crisp in which the femoral artery was tied, the average time for separation of the ligature was eighteen days, and if to this a week more were added for the closure of the wound, and for the treatment of the various accidents that often accompanied and followed ligature, we should probably be within the mark, and yet only bring the duration of the treatment by the two methods to the same level. In the present day, however, ligatures which are either absorbable, or are intended to become enclosed in the wound, are almost universally employed, and, as with the improved methods of treating wounds, union by first intention, or within ten days, is the rule, the treatment by ligature has come to be the more speedy mode of cure.

Surgeons will, however, be eventually guided in their estimate of the value of these two plans, not so much by the question of submitting their patients to a slightly more painful or tedious treatment, as by the comparative risk of life attendant upon one or other method. Upon this point statistics have yet to be made; partly because the unsuccessful cases of ligature have not been so commonly published as the successful ones, and partly because sufficient time has hardly yet elapsed since the general adoption of absorbable ligatures and of antiseptic treatment to enable us to form a correct conclusion as to the diminution in the death-rate that may be effected by their use. The following statistics, however, may be quoted as showing the average results of compression as compared with ligature and the steady improvement that has taken place in the latter operation.

In 1851, Bellingham published the results of 32 cases of femoral and popliteal aneurism treated by compression in Dublin (*Med.-chir. Trans.*, vol. 34), which may be contrasted with 188 cases of ligature of the femoral for the same disease collected by Norris in 1849. Of the 32 compression cases 26 were cured; in 1 the ligature was applied after pressure had failed,

in 2, amputation was performed; in 1, death occurred from erysipelas; in 1 from chest-disease; and in 1 case the pressure was discontinued. Thus it would appear that 6 out of the 32 failed, being in the proportion of 1 to 5.3 cases, and 2 died, being in the ratio of 1 to 16. Of the 188 cases in which the artery was ligatured, 142 were cured, 46 died, 6 were amputated, in 10 the sac supplicated, and in 2 gangrene of the foot occurred. Thus the deaths after ligature were in the proportion of 1 to 4, and the failures or serious accidents in that of 1 to 3, showing clearly a very considerable preponderance in favor of the treatment by compression. Besides this, in many patients who recovered after the ligature, various accidents, such as gangrene, erysipelas, secondary hemorrhage, etc., resulted as the direct consequences of the treatment; and these do not happen when pressure is employed.

The perfect safety of the treatment by compression was fully confirmed by the statistics collected by Holmes, and published in his lectures on the Surgical Treatment of Aneurism in 1874; but the proportion of success is not so great as in Bellingham's cases. Of 124 cases of compression for popliteal aneurism collected from the records of British hospitals for a period of 10 years, 66 succeeded and 58 failed. None died directly from the consequences of the operation. Of the 58 failures, 44 underwent ligature of the femoral, in 8 amputation was performed, one died of pleurisy, and the subsequent history of the remainder was uncertain. The failures were, therefore, 1 in 2.1. On the other hand, of 77 cases in which the femoral was tied directly, 11 died, or 1 in 7. In 1 gangrene occurred, but the patient recovered, and in 1 secondary hemorrhage was successfully treated. The 11 deaths were caused as follows: pyæmia, 3; wound of vein and phlebitis, 2; secondary hemorrhage, 2; gangrene, 1; smallpox and disease of the kidneys, 1 each, and 1 was uncertain.

Lastly, in 1883, Barwell, in his admirable article on Aneurism, in the *International Encyclopædia of Surgery*, has collected 148 cases of popliteal aneurism treated by compression between 1870 and 1880. Of these, 68 were successful, while 80 ended in failure. Of the unsuccessful cases, 57 submitted to ligature, 9 went away unrelieved, 4 suffered amputation, and 6 died. Of the 6 deaths, 2 occurred from rupture of the sac, 2 from "thrombosis," 1 from gangrene, and in one the cause was not stated. During the same period, 67 cases of ligature occurred in six of the chief London Hospitals. Of these, 10 died. If these are further subdivided, it will be found that out of 32 cases which occurred in the first half of the decade, 7 died and 2 underwent subsequent amputation; while from 1875 to 1879 inclusive, 35 cases occurred, with 3 deaths and no amputations. Whether this great improvement is merely accidental, or is the result of the improvement in the material used as the ligature and in the treatment of the wound, remains to be seen, but there is great reason to believe the latter is the true explanation.

If compression fail, ligature may often be advantageously applied; in some cases with a better prospect of success than if compression had not previously been tried, that treatment having caused the collateral circulation to enlarge, and thus lessened the tendency to gangrene. If, however, we take the general average of those cases that have been submitted to ligature after the failure of compression, we shall find that the result is not so satisfactory as when the ligature has been employed as the primary method of treatment. Thus I find that, out of 40 cases in which the ligature was employed after compression had failed, there were 16 deaths. This is probably not so much due to the previous employment of compression, as to the same causes interfering with the consolidation of the tumor after the ligature that had prevented the success of the compression-treatment. With regard to the facility of ligaturing

an artery such as the femoral, after compression has been tried and failed, it must be admitted that the difficulties are increased. The sheath of the vessels is apt to become thickened, infiltrated, and the artery and vein perhaps less easily separable than when pressure has not previously been employed. In fact, it must be said, that in such cases the Surgeon has not to do with a virgin artery.

It should also not be forgotten that in some cases, as when aneurism is complicated with heart disease, or occurs in a very broken and unhealthy constitution, in which the operation necessary for ligature would scarcely or not at all be admissible, compression may be safely employed.

After carefully considering the relative merits of the two plans of treatment, I think we may conclude that, though in some few cases neither ligature nor compression can be adopted, and amputation is the sole resource, yet in others compression can be employed when it would not be safe to have recourse to the use of the ligature; and that, in all ordinary cases of femoral and popliteal aneurism especially, compression should be preferred to the ligature, inasmuch as it is not a more tedious, and is an infinitely safer method of cure. At the same time, it must not be forgotten that its success depends very greatly on the continuous care bestowed upon the case during the progress of the treatment.

DIGITAL COMPRESSION.—Shortly after the introduction of the treatment of aneurism by instrumental compression, the fingers were used as an adjunct to the mechanical means in use. Thus Greatrex, in 1845, directed a patient to keep up compression by means of the fingers, where the tourniquet had been used, and required to be loosened. In the following year (1846) Vanzetti, then Professor of Surgery at Charkoff, tried, but unsuccessfully, to cure a large popliteal aneurism by compression of the femoral with the fingers only, continued for two days. It was not until seven years later, when Professor at Padua, that Vanzetti had an opportunity of putting this method successfully into practice, and to establish it as a distinct means of curing aneurisms. But although this merit is undoubtedly due to Vanzetti, we must credit Knight, of New Haven (U. S. A.), with the first successful case—he having, in 1848, cured a very large popliteal aneurism by digital compression, maintained for forty hours.

In this plan of treating aneurisms, no apparatus of any kind is used; but the circulation through the artery leading to the tumor is controlled by the pressure of the finger. In order to carry it out efficiently, there must be relays of assistants, each of whom compresses the vessel for about ten minutes at a time. The pressure should be applied in the way that is represented in Fig. 18, vol. i. p. 78. The fatigue may be very materially lessened by placing a 6 or 8 lb. weight on the compressing finger. With such aid each assistant may readily keep up the pressure for half an hour at a time. So soon as his fingers become fatigued, but before he relaxes the pressure, another assistant compresses the vessel; and thus the circulation through it may be uninterruptedly controlled. In this way aneurisms of the popliteal artery, in the orbit, at the bend of the arm, and in the groin, have been successfully treated—the tumor having in some instances become consolidated in a few hours. The effect of digital compression, and the rapidity of cure, would be increased by the application of direct pressure to the tumor, or by manipulation and by the previous employment of proper constitutional means, it might be very advantageously combined with the treatment by flexion. But its great advantage seems to be, that it is applicable to arteries, as those at the root of the neck, to which it might be difficult to apply any kind of compressor, and can be employed generally when no apparatus is obtainable.

ESMARCH'S ELASTIC BANDAGE has been used with a certain amount of success in the treatment of external aneurisms. It was first employed in these cases by Staff-Surgeon Walter Reid. Pearce Gould, who has investigated carefully this method of treatment, has collected the details of 72 cases in which it has been employed. Of these he finds that 35 were cured, in 30 the treatment was unsuccessful, in 5 death resulted, and in the remaining 2 the result was doubtful.

The treatment has been applied chiefly to aneurisms of the popliteal artery, but in a few cases it has been successfully employed in other situations. The objects in view are, first, to empty the whole limb of blood as far as possible, with the exception of the sac and the part of the artery in immediate connection with it; secondly, to keep the blood distending the sac at perfect rest until coagulation has taken place; and, thirdly, to protect the soft clot thus formed from the influence of the arterial current until it has become sufficiently tough and solid to resist it, by compression of the trunk leading to the aneurism. In the case of a popliteal aneurism, the treatment is thus carried out: The elastic bandage is first applied from the toes to the ham with sufficient force to render the limb bloodless; it is then carried loosely over the tumor, so as not to empty the sac, and again applied firmly as high as the middle of the thigh; the elastic tourniquet is then put on with sufficient force to arrest the circulation completely. The bandage is better left on till the tourniquet is removed. The average time required for the application of the bandage is one hour and a half. The time during which the limb may be kept bloodless with impunity is uncertain. Heath has kept the tourniquet on in one case for three hours, and in another for three and a quarter, without evil consequences; and Barwell in one case retained it for five hours. The limb must be wrapped in cotton-wool, and, if necessary, warm bottles, at a temperature of about 100° F., may be applied. The pressure causes severe pain, which may require the use of hypodermic injections of morphia; but if the treatment is continued for more than one hour, it is usually necessary to administer an anæsthetic. Before the bandage is removed, a Carte's compressor may be applied, or arrangements made for keeping up digital compression, and this must be maintained for from two to six hours, even if all pulsation has ceased when the tourniquet is taken off.

The mode by which the elastic bandage effects a cure is by causing stasis of the blood in the aneurism and the adjoining part of the artery. This stagnant blood coagulates, the clot being formed first in the aneurismal sac, and then spreading to the artery. Gould is of opinion that the permanent cure of the aneurism is effected chiefly by means of the portion of coagulum extending into the artery. This being in contact with the comparatively healthy walls of the vessel, undergoes the changes described in the chapter on Wounds of Arteries (vol. i. p. 401); the vessel is thus permanently occluded. The clot in the aneurism, on the other hand, being in contact with the unhealthy walls of the sac, or with layers of laminated fibrin, undergoes no process of organization, but tends to become friable, and to yield before the pressure of the blood, unless protected by the thrombus in the artery. If, however, the vessel be safely occluded, the sac and its contents gradually shrivel and are absorbed. Failure has in some cases apparently been due to the bandage having been applied too tightly over the tumor, so that the sac was but partly filled by the coagulum. In other cases it may have been due to a want of coagulability in the blood, and in order to avoid the possibility of this it is well to submit the patient to a course of medical treatment and diet (p. 139) before applying the bandage.

If, on removal of the bandage, there is still distinct pulsation to be felt,

although the tumor seems partially consolidated, a cure may often be effected by digital or instrumental compression in a few hours.

The chief danger to be apprehended seems to be gangrene, which has occurred in more than one case. It appears to have been due to thrombosis taking place in the vein, and possibly also in the capillaries of the parts in the neighborhood of the aneurism from which the blood had not been expelled. This, with the simultaneous occlusion of the artery, would offer an amount of obstruction to the circulation which would almost certainly end in gangrene. The only means of avoiding it seems to be by carrying the bandage lightly over the tumor, by which the veins may be emptied while the firmness of the sac is not interfered with. The expulsion of so large an amount of blood from the limb necessarily raises the arterial tension in the rest of the body; consequently the use of the elastic bandage is not to be recommended in patients affected with an internal aneurism which might rupture under the strain. For the same reason it should be avoided when there is a suspicion of fatty heart.

The elastic bandage is most likely to succeed in effecting a cure in aneurisms that are beginning to undergo consolidation. It is of little use in aneurisms that are large, rapidly increasing, with thin walls and fluid contents.

FLEXION.—The treatment of aneurism by flexion of the contiguous joint is a method that is scarcely applicable to any other form of the disease than the popliteal. The history of this plan of treating aneurisms is interesting, as an illustration of the gradual steps by which surgery usually arrives at its ultimate results. It had been long known to Surgeons that the pulse at the wrist might be arrested by the forcible flexion of the forearm on the arm; and Maigne and Richet had recommended this means for the arrest of hemorrhage from the brachial artery and the arteries of the forearm when wounded. Flury—a distinguished French naval Surgeon—having succeeded in curing a wound of the brachial artery by forced flexion of the elbow, aided by direct compression, and one of the radial by flexion of the wrist, published in 1846 a memoir, in which he stated, as a conclusion from his observations, that any aneurism of the forearm or leg might be treated by means of flexion of the limb in which it was situated. To A. Thierry is due the honor of having been the first to cure a traumatic aneurism of the bend of the arm by flexion of the limb. This was in 1852. Richet, *Dict. de Med. et de Chirurgie*, vol. ii. p. 338. In 1857, Mannair, of Geneva, applied the flexion-treatment to a large aneurism of the limb. Forced flexion could not be borne on account of the pain it occasioned, and the patient was, therefore, allowed to walk on crutches with the leg bent, and supported in a kind of stirrup attached to the opposite shoulder. In less than three weeks the cure was effected, which Mannair found a year afterwards to be permanent. In the following year, 1858, Hart applied this method of treatment successfully in a case of popliteal aneurism, and to him is due the merit of having been the first to introduce it into this country.

Flexion is necessarily applicable only to arteries situated at the bend of joints, as the elbow or ham, in which the circulation can be directly controlled by bending the limb, or in traumatic aneurisms in the limbs below these joints, in which the flow of blood through the feeding artery can be stopped in the same way. Its application is, therefore, somewhat limited, and its use is still further restricted by the pain and insupportable annoyance occasioned in many cases by forced flexion of the limb, necessitating, as in Mannair's case, a relaxation of the method, which, however, was still effective in curing the aneurism.

Nothing can be simpler than the details of this plan. It consists, in the lower limb, in applying a bandage as high as the knee and then gradually flexing the leg upon the thigh, so that the heel is brought up towards the buttock, where it is retained by a strap or bandage. The patient is at the same time confined to bed, and put under proper constitutional treatment. By this means, the popliteal artery being bent at an acute angle, the circulation through it is nearly, if not completely arrested; and the obstacle to the flow of blood is still further increased by the compression of the tumor between the posterior flat surface of the femur and the upper part of the calf. In this way the aneurism is most favorably situated for the consolidation of its contents, which, in the recorded cases, has often taken place at an early period.

The principle on which the cure is effected in these cases appears to be, that by flexion the artery leading to and from the sac, and the aneurism itself, are so compressed that retardation of the circulation ensues, and deposition of laminated fibrin takes place in the usual way.

The compression by flexion, like every other method of treating aneurisms, occasionally fails. It is most likely to be attended by success in those cases in which the aneurism is small, situated low in the popliteal space, and in a young or middle-aged subject, who can bear the continued flexion without much inconvenience.

When flexion is not sufficient of itself to cure an aneurism, it may very advantageously be had recourse to in addition to other methods of treatment, more especially with that by digital compression.

The statistics of the treatment by flexion require to be carried down to the present time. Those published by Fischer in 1870, comprised 57 cases. Of these 28 were cured—20 being by flexion alone; and in 29 the method failed.

The various methods of employing compression, viz., by clamps, by weight, by flexion, and by the finger, may often be advantageously combined in the same case. When the patient tires of one, another may be substituted for it; and thus the good effects continuously kept up with less fatigue and irritation than would otherwise be experienced. So also various modifications of these different methods may be practised to suit the requirements of any particular case. But for these no special directions can be given; the ingenuity of the surgeon must supply the want in each case.

COMPRESSION BY ACUTE-RISSURE of the main artery leading to the sac is a means that, I think, might in certain cases be temporarily employed with advantage, and the consolidation of the aneurism thus obtained in cases where compression by the ordinary methods, digital or instrumental, is not practicable. With this view a long and strong curved needle, such as the stilet of a piston-trocar, might be dipped deeply under the artery and vein—e.g., the common femoral, and the artery compressed against this by means of a cork and twisted suture for several hours—the vein being left free. The patient might be kept under chloroform, if necessary. When consolidation of the contents of the sac was obtained, the compressing means might be removed. Such a method of treatment might possibly be advantageously combined in certain extreme and exceptional cases with the injection of the sac with the perchloride of iron, or the use of electro-puncture.

MANIPULATION.—Sir W. Fergusson proposed to treat some aneurisms by a procedure which he termed *manipulation*. This consists in squeezing the aneurismal tumor in such a way as to detach a portion of the coagulum within it, which, being carried on with the current of blood into the distal end of the artery, obstructs this; and thus, by impeding the circulation

through the sac, may lead to the gradual consolidation of the tumor; and it has also been suggested by Oliver Pemberton that the alteration of the relations of the laminated fibrin in the cavity of the aneurism may bring about a further deposition of fibrin on the displaced laminae. This procedure has as yet been employed to too limited an extent to enable us to form an estimate of its value, and can scarcely be considered, nor is it intended to be, of very general application. To aneurisms, however, that are not amenable to ordinary surgical treatment, and that must necessarily prove fatal if left, as those situated at the root of the neck, more particularly of the subclavian artery, it might possibly be advantageously applied. It is scarcely necessary, however, to point out the obvious danger of rupture of the sac, or of the diffusion of the aneurism from the weakening of its walls by the separation of the coagulum, to make Surgeons adopt due caution in carrying out this method of treatment. There is another danger also especially attendant on this procedure, when applied to aneurisms about the neck; viz., that the detached coagulum may be carried by the circulation into the cerebral arteries, and by obstructing them occasion the same kind of cerebral disturbance that occurs when these vessels become occluded by fibrinous plugs—emboli. That this danger is a real and a great one, is evident from the fact that, in some cases in which manipulation of subclavian and carotid aneurisms has been tried, the patient has been suddenly seized with syncope and hemiplegia. Teale has successfully conjoined manipulation with compression in a case of popliteal aneurism, in which the pressure on the artery was slow in consolidating the tumor; the detachment of a portion of the coagulum almost at once led to the consolidation of the tumor. Somewhat analogous to this method is one recommended in 1842 by Blake, who proposed, by the introduction of a cataract-needle into the sac, to detach some of the laminated fibrin, which might then be washed against, and occlude the aperture of exit.

GALVANO-PUNCTURE.—The attempt to procure the consolidation of an aneurismal sac by the employment of electricity is of comparatively recent date. It appears to have been first practised by B. Phillips, about the year 1832. Little attention, however, was given to this mode of treatment until a few years back, when it was revived by some of the French and Italian Surgeons, especially Petrequin, Barci, and Ciniselli. The object aimed at by this operation is the production of coagulation in the aneurismal sac by decomposition of the blood contained in it by means of the galvanic current. When two needles connected with the poles of a galvanic battery are introduced into a mass of fluid blood, a firm solid coagulum is rapidly formed round that connected with the positive pole, while at the same time a large, soft, spongy clot mixed with bubbles of gas is seen at the negative needle, and a dark, tar-like fluid also makes its appearance. If the needle used be made of steel or any other readily soluble metal, further changes occur at the positive pole due to the production of salts of iron with the acids liberated from the blood. These changes are spoken of as secondary electrolysis. The clot formed by electrolysis is, therefore, not composed simply of the fibrin of the blood, but contains also a large proportion of albumen coagulated by the chemical action of the current, and must be looked upon as a foreign body around which we hope ordinary coagulation will occur.

The operation of galvano-puncture is best performed as follows. Two steel needles, well insulated with vulcanite or gum-elastic, are inserted into the sac of the aneurism and connected with the opposite poles of the battery. The needles should be about one inch apart, parallel to each other, and so inserted that no part of the uninsulated portion of the needle shall touch

the sac. The best battery for the purpose is one of the ordinary medical batteries with small Leclanche cells, of which from ten to twenty may be used for a time varying from twenty minutes to half an hour, or more—according to the effect produced. If the tumor be sufficiently near the surface to be clearly observed, as has been the case in several of the aneurisms in which the treatment has been employed, it will be seen to become more tense and firm, and the expansile nature of the pulsation will become diminished as the operation progresses. Sometimes bubbles of gas escape by the side of the negative needle, and a little thick brown fluid oozes up. Occasionally the tumor has been found to swell and become resonant on percussion. When a distinct effect has been produced the needles may be withdrawn, and the small punctures closed with lint and collodion. The negative needle will be found unaltered, while the positive will be corroded directly in proportion to the amount of electrolytic action that has taken place. In order to prevent this corrosion of the positive needle, it has been suggested by Dr. John Duncan that platinum may be used instead of steel. There is no evidence, however, to prove that the salts of iron produced give rise to any particular danger; in fact, it is probable they aid considerably in the formation of the firm coagulum surrounding the needle. The battery used in the operation is of considerable importance. It has been pointed out by Glimmelt that a current of high tension and somewhat low intensity is less likely to cause the production of undue heat during the operation, and consequently less prone to lead to inflammation and suppuration of the sac. A battery, therefore, composed of a large number of small elements is superior to one of a few large elements. Some operators, and especially Bastian, have advocated the introduction of the positive pole only, the negative being attached to a sponge or metal plate laid on the skin near the aneurism. The only objection to this mode of treatment is the excessively small effect produced. The electrolytic action which takes place is directly in proportion to the intensity of the current; and by the introduction of a considerable mass of the tissues of the patient in the circuit, the resistance is so greatly increased that electrolysis is reduced to a scarcely appreciable amount, the positive needle appearing almost unchanged after the operation. Others, again, have introduced the negative needle only, but as the coagulum formed at the negative pole is soft and frothy, but little good can be expected from this mode of operating. Dr. Julius Althaus, who has superintended the operation in five cases, is strongly of opinion that "the most effective application of the current is that where both poles are inserted into the sac." Glimmelt operated in this way, and Drs. Duncan and Fraser, to whom we are indebted for many important observations on galvano-puncture and for the invention of reliable insulated needles, support the same view. The operation is accompanied by but little pain, and it is only occasionally that chloroform is needed. The effect of a single operation is seldom sufficient to cause any marked improvement in the condition of the patient, and it requires usually to be repeated several times.

The clot formed as the result of galvano-puncture is somewhat soft and yielding, and unless supported by a moderately firm sac soon flattens out or retracts, and the condition of the aneurism becomes much the same as it was before the operation. Little more than the most temporary relief can for this reason be expected in many cases; and whenever the aneurism has become diffused, the operation can only be productive of mischief by hastening the inflammatory changes occurring round the sac. It might be supposed that so soft a clot would readily break up, and that the danger of embolism would be great in consequence; but experience has shown that it

is not, no such accident having happened in any of the recorded cases. Suppuration of the sac has occasionally occurred, but its occurrence has been much less frequent since the principles of the operation have been more fully understood. The formation of sloughs round the needle-punctures, and consequent hemorrhage, has not been noticed except when the needles have been imperfectly insulated. In fact, it may be said that in almost every case, even when the operation has failed to give relief, it has at any rate done no harm.

The statistics of the operation have not been fully compiled, but the general results of the published cases have not been unfavorable when we consider the hopeless nature of the cases in which it has been performed. Of 13 cases of aneurism of the aorta treated by Ciniselli's method, five were cured, and no evil consequences followed in any case. Of the same number which have been operated on in this country during the last few years, none have been cured, but at least six experienced more or less relief; and in almost all, it may be said, the operation aimed only at relief, the disease being too advanced to warrant any hope of cure. About sixty other cases of aneurism of various arteries have been collected by Ciniselli as having been operated on before 1868; but in these the methods used were so imperfect, that they cannot be fairly considered as bearing upon the question at the present time.

When we compare galvano-puncture with ligature or compression in the treatment of external aneurism, it is, I think, impossible to hesitate for a moment in giving a decided preference to the latter modes of treatment, as the results that have hitherto been obtained are not such as would justify a prudent Surgeon in submitting his patient to an operation of this kind, when he possesses such certain and comparatively safe modes of treatment as deligation or compression. In internal aneurisms, or in those cases in which the disease is so situated at the root of the neck, that the artery can neither be ligatured with safety nor compressed, galvano-puncture is certainly justifiable, especially when conjoined with proper medical treatment, as we have ample proof that with the knowledge and means now at our disposal we can perform the operation with scarcely any danger to the patient, and in favorable cases with some hope of relief. Much will depend upon the selection of the case. Ciniselli has pointed out that the conditions favorable to success are, that the aneurism shall be sacculated and opening into the vessel by a narrow mouth, of slow growth and of medium size, and, when thoracic, situated entirely within the thorax, and that it shall not in any serious way have interfered with the general health of the patient. These conditions seldom occur; and when they are absent, the most that can be hoped for is temporary arrest of the progress of the disease and some relief to the patient's sufferings.

INJECTION WITH PERCHLORIDE OF IRON.—The injection of aneurismal sacs with a solution of the perchloride of iron has also been practised, with the view of coagulating their contents; such treatment, however, is attended with great risk of embolism, and is in every way vastly inferior to the ligature or compression of the artery leading to or beyond the sac, and should never be employed if these can be practised.

Aneurism of the gluteal artery has been successfully treated by injection of the perchloride of iron in at least one case. In cases, however, in which, either from the situation of the disease, its complication with other and extensive disease of the arterial system, or its multiple character, ligature and compression are not applicable, an endeavor might be made to procure the clotting of the blood in the tumor by distal compression of the artery, before

attempting to coagulate its contents by injection of the perchloride; and I cannot but think that a satisfactory result might thus be obtained.

HYPODERMIC INJECTION OF ERGOTIN.—Langenbeck advocated the hypodermic use of a watery extract of ergot in cases of aneurism, under the impression that it might act on the muscular fibres scattered over the sac of the aneurism in the same way as it acts on the muscular fibres of the uterus, and by causing contraction might gradually diminish the size of the aneurism, if not cure it. He seems to have tried it in two cases only. One was an aneurism in the supraclavicular region (exact nature not mentioned), which had been previously treated with moxas, and almost cured. The symptoms having returned, hypodermic injections of ergot were tried. The quantity injected varied from about $\frac{1}{4}$ grain to 3 grains of Bonjean's watery extract of ergot, diluted with three times as much spirit and glycerine. The injections were repeated every three or four days. Decided improvement is said to have occurred, but pulsation never quite ceased. The improvement commenced after the second injection. No unpleasant symptoms occurred after the injections. In the second case a man, aged 42, had a sacculated aneurism of the radial artery of the size of a hazelnut. An injection of two grains and a half of the watery extract cured it in one day, as the next day it could not be felt. The injection gave rise to some inflammation of the surrounding cellular tissue which disappeared in a week.

This accident I have seen happen in one case in which I tried it, but no good resulted from the treatment, which cannot, indeed, on pathological grounds, be considered to be of a hopeful character.

INTRODUCTION OF FOREIGN BODIES.—The introduction of foreign bodies of various kinds into the sac has been attempted in a considerable number of cases with the view of producing an artificial coagulum in the aneurism. Thus coils of horsehair, catgut, or iron wire have been thrust into and left in the sac, through a puncture made in it. The results of these operations have not been such as to justify a repetition of the treatment.

ACUPUNCTURE with very fine needles has, however, been performed with some benefit in a few cases, and if carefully carried out, can hardly be productive of any injury. It was first suggested by Velpeau, and practised without success by Dunville and Agnew. Marshall has in more than one case obtained in this way some consolidation in aortic aneurisms, and MacEwen succeeded in curing a popliteal aneurism by the introduction of a fine needle while the femoral artery was compressed. Heath attempted the same treatment in a case of subclavian aneurism in University College Hospital after he had unsuccessfully amputated at the shoulder-joint. Six fine needles were introduced into the sac in such a way as to cross each other, and were left in for four days, at the end of which time the tumor was much firmer. The patient died about twelve days after from causes unconnected with the treatment, and a considerable amount of firm clot was found in the sac. This treatment seems worthy of further trial in otherwise hopeless cases as a substitute for galvano-puncture. The smallest sewing needles with heads made of sealing-wax may be used, as in Heath's case; or better still, the fine pins known as entomological pins, which should be gilded. They may be left in for from four to five days, and it is perhaps safer to cover them with some simple antiseptic dressing to diminish the risk of ulceration. After they are removed the punctures must be covered with collodion.

ARTERIO-VENOUS ANEURISM.

Preternatural communication between arteries and veins, though usually the result of wounds, occasionally happens from disease; ulceration taking place between the vessels, and thus causing an aperture to lead from one into the other. When such communications are of a traumatic origin, they may, as has already been stated, constitute either an *Aneurismal Varix* or a *Varicose Aneurism*. As the result of disease, aneurismal varix only can occur, varicose aneurism never happening except as a consequence of wound. These spontaneous communications have been met with between the aorta and the vena cava, and between the iliac, femoral, carotid, and subclavian arteries and their accompanying veins. In nature, symptoms, course, and treatment, they so closely resemble traumatic aneurismal varix, described at p. 450, vol. i., that their consideration need not detain us here.

SPECIAL ANEURISMS.

CHAPTER XLIV.

ANEURISMS OF THE THORAX, HEAD AND NECK, AND UPPER EXTREMITY.

ANEURISM OF THE THORACIC AORTA.

SYMPTOMS.—The symptoms of Intrathoracic Aortic Aneurism are of two kinds: *auscultatory* and *rational*.

The **Auscultatory Signs** vary greatly in distinctness, and may even be wanting. In some cases, more especially in fusiform aneurisms, they are almost from the first of a very marked and obvious character; in others, especially in sacculated aneurisms, they may be absent throughout, the aneurism terminating fatally without its existence having been determined by the stethoscope. They consist in murmurs of various kinds and degrees of intensity—bellows, rasping, or whizzing; in the second sound of the heart being audible over a greater space than normal. At the same time there may be dulness on percussion. These various signs may often be heard more distinctly upon or to the left side of the spine, than at the anterior part of the chest; when occurring anteriorly, they are chiefly met with on the right side.

The value of the auscultatory signs in the diagnosis of aneurism within the chest is not perhaps so great as in many other thoracic diseases, in the early stages of the affection, and in those cases in which the aneurism continues small and sacculated throughout, or is so deeply seated as not to approach the parietes of the chest. This need not be a matter of surprise, when we reflect how deeply the ascending portion of the aorta and the arch are situated; how they are covered in front by the lungs and loose areolar tissue, through which sound is with difficulty transmitted; and how they are covered in behind by the spine and its muscles. When, in addition to this, it is borne in mind that aneurisms of the arch often prove fatal by bursting into contiguous cavities and canals before they have attained a size greater than that of a walnut or a pigeon's egg, and thus are incapable of furnishing a murmur of any very marked kind, it can be easily understood that the value of auscultation is but small in many cases of thoracic aneurism.

The **Rational Signs** of intrathoracic aortic aneurism are of three kinds: Pressure-effects; Pulsation; and Tumor.

Pressure-effects may be exercised on any of the contiguous structures; and a glance at the anatomical relations of the thoracic aorta, more particularly the arch, will enable the Surgeon to judge of their complexity and importance. They will necessarily vary according to the size of the aneurism and the portion of the aorta affected by it; more according to the latter than to the former condition. When the aneurism arises from the *root of the aorta*, and more especially when it is intrapericardial, it is usually of small

size, and its pressure-effects will be little obvious. When the aneurism arises from the *termination of the arch*, or the *descending aorta*, it may often attain a considerable development without causing any very obvious pressure-effects. Aneurisms that are situated *within the concavity of the arch* necessarily give rise to very severe effects, by the compression they must exercise upon some one or other of the very important structures that are included within the aortic arch. When the *anterior part of the aorta* is affected, the aneurism may attain a very considerable bulk, even coming forward so as to project and pulsate between the intercostal spaces, without any very noticeable pres-

Fig. 463.—Erosion of Intervertebral Substance by a small Aneurism of Descending Aorta pressing backwards.

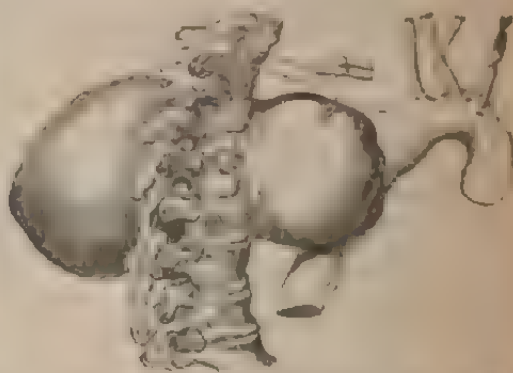

Fig. 464.—Aneurism of Descending Aorta, encircling and traversing Vertebrae.

sure-effects being induced. But when the *posterior wall of the artery* is the seat of the disease, then severe symptoms are early set up by the compression and erosion of the structures lying contiguous to the artery and along the spine, (Fig. 463). When the *upper part of the aortic arch* is the seat of aneurism, a peculiar train of cerebral symptoms, such as vertigo, insensibility, or defective vision, may be induced by its interference with the circulation through the carotids.

The pressure-effects that need chiefly engage our attention, are, 1, Pain; 2, Dyspnoea; 3, Dysphagia; and, 4, Oedema.

1. **Pain** is usually one of the earliest symptoms of intrathoracic aneurism, and is frequently of great value in a diagnostic point of view, as it is often most marked when the other symptoms are the least developed. It is generally more severe in sacculated than in fusiform aneurisms, and when the posterior rather than the anterior aspect of the vessel is the seat of disease. The pain is of two distinct kinds. The first kind is lancinating, intermittent, and neuralgic in its character, evidently dependent upon pressure on the spinal or sympathetic nerves. This pain is seated chiefly on the left side, and shoots up the side of the head and face, along the upper arm to the elbow, along the intercostohumeral nerve, through the chest, or between the scapulae. The second form of pain occurs usually at a later stage of the disease, is continuous, and of a boring, hot, or burning character. It seems to depend upon the perforation of the tissues, more especially the bones, by the aneurismal tumor, and occurs chiefly on the right side of the chest (Fig. 464).

2. **Dyspnoea** is of very frequent occurrence in intrathoracic aneurism; in all probability it is more uniformly met with than any other single symptom. It may arise from five distinct conditions, and its characters vary with its cause.

a. *From direct pressure on the trachea.* In these cases the dyspnoea is attended by much wheezing cough, and often by whistling sounds in the chest and tubular respiration, and by slow expansion of that cavity. There is usually expectoration of thick tenacious mucus.

3. *From direct pressure on a bronchus* (Fig. 465). In these cases there are wheezing, cough, and some degree of expectoration, with, perhaps, diminished respiratory murmur in the side affected, and puerile respiration in the opposite lung, as has been pointed out by Stokes.

4. *From pressure upon the lung.* In these cases the respiration is comparatively little interfered with, the spongy tissue of the lung accommodating itself and yielding to the pressure of the tumor. After a time, the pulmonic tissue will become incorporated with the wall of the sac; and then more serious difficulty in breathing, with hæmoptysis, will supervene.

5. **Dyspnoea** is very commonly induced by irritation, compression, or stretching of the left pneumogastric and recurrent laryngeal nerves, by the pressure of the tumor. In these cases the muscles that are supplied by the left recurrent laryngeal nerve may be paralyzed, so as to occasion attacks of intense difficulty of breathing. In many cases spasm occurs from irritation of the nerve before it is pressed on sufficiently to cause paralysis.

It is the *crico-arytenoideus posticus* muscle that is chiefly affected by the compression of the recurrent laryngeal. As its action is to open the glottis, its paralysis causes an impediment to the entrance of the air by the collapse of the left side of the rima glottidis—hence the dyspnoea and struggle for breathing under exertion. The voice becomes hoarse, croupy, or croaking; the cough has a loud croupy or metallic sound, and is attended by the expectoration of thin frothy mucus. The laryngeal stridor often does not occur in ordinary respiration, but is produced under exertion, or on making the patient inspire fully and deeply. The laryngeal symptoms are sometimes so much more prominent than any of the other signs of intrathoracic aneurism, and so closely resemble chronic or even acute laryngitis, with impending asphyxia, that there are not a few cases on record in which Surgeons have performed tracheotomy, on the supposition that they had to do with cases of pure and uncomplicated laryngeal disease; and, in other instances, this operation has been performed with a view of prolonging life,

Fig. 465. — Aneurism of Arch of Aorta, of the size of an almond, springing from below left Subclavian Artery, and bursting into left Bronchus.

even when the dependence of the laryngeal spasm on aneurism of the aorta has been recognized.

Dr. George Johnson has made some important observations on the use of the laryngoscope in the diagnosis of the cause of dyspnea in aortic aneurism. He says that, in cases where the cause is pressure on the recurrent laryngeal nerve, the larynx is seen to be healthy, and the spasm may be seen to occur. If the pressure be sufficient to abolish the function of the nerve, unilateral paralysis will occur, which can be easily ascertained by laryngoscopic examination. The voice in such cases is weak and husky; whereas, in cases in which the pressure is on the trachea, its character is unchanged. When a thoracic aneurism presses the trachea against the spine, the tracheal stridor and the voice-sound are heard with remarkable distinctness on applying the stethoscope over the upper dorsal vertebra—the sound being conducted through the bones.

Dyspnea may be dependent on *compression of the pulmonary vein* by the aneurismal tumor. In cases of this kind there would be considerable lividity of surface, and signs of pulmonary congestion.

The dyspnea of intrathoracic aneurism will often be sufficiently intense to occasion death. It may be mistaken for ordinary asthma; but the diagnosis can usually be effected by observing that in aneurism the paroxysms of dyspnea often come on in the day as well as at night, and are greatly increased by change of position, as by placing the patient either upright or recumbent, the tumor thus shifting its point of pressure. It is, as Bellingham has pointed out, not influenced by atmospheric changes, and is generally associated with laryngeal stridor or spasm. When such symptoms as these are associated with pain and dysphagia, they point very strongly, even in the absence of all auscultatory signs, to the presence of an aneurismal tumor.

Aneurisms situated within the concavity or springing from the posterior parts of the aortic arch are those which, either directly by their pressure on the air-tubes or the pulmonary veins, or indirectly by the influence they exercise on the recurrent laryngeal nerve, are chiefly associated with dyspnea.

3. **Dysphagia** is a symptom of sufficiently frequent occurrence in aneurisms of the thoracic aorta. Eaton has determined its existence in nine out of twelve cases. It seldom occurs, however, in the earlier stages of the disease, or when the aneurism is small, and hence is of much less diagnostic value than dyspnea. When, however, it is associated with that symptom, the combination becomes important; as the coexistence of the two conditions clearly points to the compression of the œsophagus and the air-tubes by a tumor, which other diagnostic signs may prove to be aneurismal.

It is of importance to bear in mind that in some aneurisms, especially of the descending thoracic aorta, dysphagia may be one of the most marked signs. In such cases as these, stricture of the œsophagus has erroneously been supposed to exist, and the patient has even been treated by the introduction of bougies on this supposition—an error of practice that has terminated fatally from perforation of the aneurismal sac, where it projected against the œsophagus, by the point of the instrument.

The difficulty in deglutition, in cases of compression of the œsophagus by aortic aneurism, is almost invariably referred to the episternal notch. The dysphagia is commonly associated with pain, or with the sensation of a cord drawn tightly around the body.

4. **Edema**, with more or less lividity of the upper extremities and head and neck, occasionally but rarely occurs. It is generally most marked on the

left side, and arises from the compression of the superior cava or the innominate veins by aneurisms springing from the fore or upper part of the arch.

Pulsation and Tumor, observable externally, are always absent in the early stages of intrathoracic aortic aneurism, and very frequently continue so throughout the progress of the affection; indeed, in aneurisms springing from the intrapericardial aorta or the concavity of the arch, death usually takes place, either by rupture into one of the serous cavities or the air-tube, or by the exhaustion induced by dyspnoea, long before the aneurism has attained a sufficient size to be recognizable externally. There are, however, three portions of the thoracic aorta which, when affected by aneurism, yield external evidence by the existence of pulsation or tumor of the true nature of the disease. These are—1, the anterior aspect of the ascending aorta; 2, the summit of the arch; and, 3, the posterior aspect of the descending aorta.

1. When the aneurism is situated on the anterior aspect of the ascending aorta and commencement of the arch, pulsation may be detected by pressure between the intercostal spaces on the right side of the sternum, and a thrill, as well as distinct impulse, may often be felt over that side of the chest, before any external tumor becomes visible; thus simulating the beat of the heart, in addition and opposite to the seat of the true cardiac impulse. As the aneurism increases an external tumor appears, the wall of the chest becoming absorbed and perforated opposite the point of greatest impulse.

2. When an aneurism springs from the summit of the arch, a pulsating tumor appears at the root of the neck, behind or even above the margin of the sternum, most commonly towards the right side, and occasionally rises so high out of the thorax, and is so distinctly felt in the neck, as to run the risk of being confounded with aneurism of the brachio-cephalic or carotid artery (Fig. 470, p. 189). This error, which has frequently been committed, and which has led to operations on the arteries at the root of the neck, may usually be avoided, except in the case of the brachio-cephalic, by the impossibility of tracing with the finger the lower boundary of the tumor, and the existence of distinct dulness on percussion, and possibly of impulse or of auscultatory evidence of aneurism, below the level of the upper margin of the sternum or clavicle.

3. When aneurism springs from the posterior wall in the descending aorta, a pulsating tumor may gradually develop to one side of the spine or under the scapula, commonly on the left side; and it may attain an excessive size, fully as large as the head (Fig. 464), before the patient is destroyed by the rupture of the tumor externally.

TREATMENT.—In the great majority of aneurisms of the thoracic aorta surgical interference is impossible, and our sole reliance must be placed on rest, diet, and the administration of iodide of potassium (see p. 140).

Surgical Treatment of Aneurism of the Aortic Arch.—The idea of treating aneurism of the aortic arch by ligature of one or two of the main arteries at the root of the neck, originated in the results of an operation performed by Christopher Heath in 1865 for the cure of a supposed innominate aneurism by the simultaneous ligature of the right carotid and subclavian arteries. The patient, a woman of intemperate habits, survived the operation for four years, appearing for a time to have been benefited by it. On her death it was found that the aneurism was not one of the innominate but of the ascending aorta, and that it had been practically cured by or after the operation. Dr. Cockle about the same time was engaged in a series of interesting observations on the spontaneous consolidation of aneurisms of the aortic arch, he found that in some of these cases the left carotid artery had become occluded, and he inferred from this pathological fact that ligature of that vessel might be of use in the treatment of certain forms of aneurism of

the arch. This suggestion was acted on by C. Heath, who, in 1872, tied the left carotid artery in a patient of Dr. Cottle's affected with aneurism of the ascending and transverse portions of the arch. The patient was benefited by the operation. Barwell has operated in two cases, in one with advantage. In the other, in which the left subclavian was also tied, the patient died, apparently uninfluenced for good or ill by the operation. Heath's second case of ligature of the left carotid proved fatal by syncope. In all, the operation appears to have been done 13 times (Ashhurst)—in six cases with more or less benefit. In at least four of these cases the artery was ligatured on the supposition that the aneurism was situated at the root of the carotid, when, in reality, it occupied the arch. Barwell states that, in those aneurisms which spring from the aorta beyond the left carotid, ligature of this vessel will do more harm than good, and that the operation should be confined to those in which the tumor appears on the left side, but not far from the median line, and rises into the episternal notch or under the left sternomastoid.

The Simultaneous Ligature of the Right Carotid and Right Subclavian Arteries for aneurism of the aortic arch has, according to Barwell, been done in three cases only for aneurism diagnosed as aortic before the operation. In some other cases, as the one referred to above, diagnosed erroneously as innominate, but proving in reality to be aortic aneurism, it has also been done. In the three cases of recognized aortic aneurism the operations were done by Barwell, Lediard, and Wyeth. In all, the "ox-aorta ligature" was used, and the patients lived 15 months, 84 months, and 1 year respectively after the operation (Barwell).

The ligature of one or more of the main arteries at the root of the neck for the cure of aneurism of the aortic arch involves a new principle in the treatment of that disease: one that differs in all respects from that in which the cure of an ordinary external aneurism is effected. By whatever way the Surgeon acts, whether by the Hunterian or the distal ligature, by compression with instrument or finger, he seeks one common result, viz., the arrest or retardation of the circulation through the sac so as to facilitate the deposit of laminated fibrin or firm clot. He usually acts directly upon the artery that is the seat of the disease, and in all cases of the Hunterian operation, or of arterial compression, the supply of blood sent into the sac is most materially diminished, if not altogether arrested. But in the treatment of aortic aneurisms by ligature of the left carotid only, or by that of the right carotid at its root, and of the right subclavian in the third part of its course, he not only does not diminish or retard the flow of blood through the aorta or lessen the quantity sent into the aneurismal sac, but as the volume of blood ejected from the left ventricle at each systole continues unchanged, a larger blood-stream must actually be thrown into the aorta beyond the point at which the deligated vessel is given off, equal in amount to what would normally have passed into the artery that has been tied. By thus increasing the volume of blood in that portion of the arch of the aorta beyond the giving off of the ligatured artery, an increased pressure will be thrown upon the whole interior of the vessel and of any aneurismal sac that springs from it. Thus, the very reverse of what happens in the Hunterian or ordinary distal operation, takes place when one or more of the primary branches of the aortic arch is tied. And if a cure of an aneurism in this situation be thus effected, it must be on a new principle, different from any that has yet guided the Surgeon in the treatment of this disease.

That some benefit appears to have followed these operations in a few of the cases is undoubted: but how much of this may be fairly attributed to the direct influence of the operation appears to me to be very uncertain. For it cannot be doubted that the confinement to bed after the operation, and

the more careful and regulated life that would be led by those who had been subjected to so serious a procedure, must exercise a very directly beneficial influence upon any internal aneurism; and it may fairly be a question whether an aneurismal patient, subjected to an operation that would require confinement to bed or at least absolute quietude for several weeks and subsequently necessitate a quiet and carefully regulated life, would not derive as much benefit as have the patients in whose necks large arteries have been tied for the cure of aortic or even of most innominate aneurisms.

The necessity for hesitation in the adoption of these operations for the cure of aortic aneurism appears to me to be strengthened by the acknowledged difficulty in effecting a correct diagnosis, in many cases, of the exact seat of the aneurism, whether it be innominate or aortic, or both, or, if aortic, from what part of the arch it springs; and also in determining with absolute certainty whether a given intrathoracic tumor be an aneurism or not.

The immediate danger of these operations, whether done for aortic or innominate aneurism, is also very considerable. A very large proportion of the patients so operated on died within a fortnight, and in some cases death resulted immediately or within a few hours consequent on the disturbance of the circulation through the brain by the ligature of one of the greater arteries springing from the arch.

Another fact of much importance that cannot be ignored in considering the advisability of subjecting a patient with supposed aortic aneurism to the operation of ligature of the carotid and subclavian arteries is the undoubted very slow progress and prolonged duration of many of these aneurisms, and the possibility of a spontaneous cure in some. Patients with aortic aneurisms frequently live for several years after the disease has been recognized. Under proper constitutional treatment the severity of the symptoms may be greatly mitigated, and in all probability the chances of cure would be about equal under the two modes of treatment—the strictly surgical and the medical—whilst that of speedy or of sudden death would be more likely to occur to those subjected to the operation.

Some Surgeons have tried to obtain consolidation of the tumor by coagulating its contents by thrusting coils of iron-wire or catgut into its interior, but it need scarcely be said that in no case has any permanent success attended such procedures.

The rapid solidification of a large aortic aneurism is not unattended by danger; so long as the contents are fluid the patient goes on fairly well, but if they rapidly solidify the pressure of the tumor leads to great distress and rapidly hastens the patient's death.

The mode of treatment which has been more frequently adopted in aortic aneurism than any other is **galvano-puncture**; and in well-selected cases this may be productive of considerable good, or even occasionally lead to a complete cure. In 27 cases of aortic aneurism thus treated, which have been collected by John Duncan, 5 were cured, 10 relieved, 9 unrelieved, and 3 died. Experience has shown that with the latest improvements in the operation—well-insulated needles and a suitable battery—there is scarcely any danger to life, and that, even where it does no good, it does no harm. It has been applied in all stages of the disease, from the time when the tumor becomes sufficiently superficial to allow the safe introduction of the needles, to the time when it has perforated the chest-wall, and is on the point of bursting. In one of John Duncan's cases, the life of the patient was undoubtedly prolonged for nearly three months after the time at which, if left to itself, the aneurism would have burst externally. The cases best suited for galvano-puncture, and in which even a cure may be occasionally hoped

for, are those in which the tumor is of slow growth, has not yet perforated the chest-wall, and in which it can be diagnosed as sacculated and communicating with the aorta by a comparatively small opening. It is important also that the patient's health should not be too much broken by suffering or visceral disease. When the tumor projects through the parietes of the thorax, forming a secondary sac outside, the prospect of cure is infinitesimally small; but even then, progress may be delayed, and much relief given to the patient. If the tumor have become diffused, as may occur when it points in the back, galvano-puncture can only do harm by increasing the tendency to inflammation and suppuration already existing. For the details of the operation, see page 168.

There is one point in the treatment of some forms of aortic aneurism, that falls within the province of the Surgeon, and on which his opinion may be sought. I mean the advisability of opening the windpipe, to relieve the patient from the distress occasioned by the laryngeal spasm that commonly attends many of these cases. The decision of this question is always an anxious one; for it must be borne in mind that, as the disease that occasions the spasms of the larynx is necessarily and inevitably fatal, the operation can be expected to give only temporary relief, and at most but a brief prolongation of life.

In determining this question, the Surgeon must bear in mind that simple laryngeal spasm is rarely, if ever, the cause of death in aortic aneurism; that, although the patient may suffer greatly from this complication, he does not die of it; but that the ultimate cause of death is usually intrathoracic pressure, rupture of the sac internally or externally, or exhaustion. The operation, therefore, would be justifiable in those cases only in which it could be determined that the spasmodic dyspnoea was purely laryngeal, and was not dependent on compression of the air passages within the chest by the aneurismal tumor, but simply on the irritation produced by the implication of the left recurrent laryngeal nerve. Such cases are very rare pathologically, and necessarily most difficult of accurate diagnosis. As the Surgeon will usually get the credit of having killed the patient if he be induced to perform the operation, and the relief be not immediate and great, I would advise him not to operate unless the diagnosis be most clear, or in circumstances of imminent death from uncomplicated laryngeal spasm, with the view of affording immediate, even if it be temporary, relief. If any operation be done, it should certainly be laryngotomy, and not tracheotomy.

ANEURISM OF THE INNOMINATE ARTERY.

Aneurisms of this artery are very frequently accompanied by dilatation or actual aneurism of the aorta. Innominate aneurisms may be either of the tubular or the sacculated kind, and usually give rise to a train of serious and dangerous symptoms, from their pressure upon important parts in their neighborhood. Indeed, a glance at the relations of this artery will show the important effects that must be produced by the pressure of a tumor springing from it. Before it lies the left innominate vein, to the outer side are the lower cervical cardiac branch of the pneumogastric, the right innominate vein, the right pneumogastric and the pleura; behind it and to its inner side is the trachea. An aneurismal tumor of the innominate artery may extend backwards so as to come into relation with the oesophagus, and upwards so as to press on the right recurrent laryngeal.

SYMPTOMS.—The general symptoms of an aneurism of this artery are the existence of a pulsating tumor of a globular shape behind the right sterno-

clavicular articulation, attended with pain, and perhaps oedema of the right side of the face and arm, with some difficulty in respiration, laryngeal cough, and dysphagia. The tumor is usually soft and compressible, filling up more or less completely the hollow above the sternum, and even rising as high in the neck as the lower margin of the cricoid cartilage; it pushes forwards, first the sternal, and afterwards the clavicular portion of the sterno-mastoid muscle, and has occasionally been seen to extend into the posterior inferior triangle of the neck; and, indeed, is generally most distinctly defined towards its brachial aspect. In some cases no tumor rises into the neck, but the sternum, clavicle, and costal cartilage of the first rib, are found to be considerably pushed forwards beyond their natural level. In the space around the right sterno-clavicular articulation, and about the upper part of the sternum, there will be dulness on percussion, and marked pulsation is often felt in the first intercostal space. In very many instances there is no bruit, but merely a strong impulse with the heart's sounds, as distinct as in the cardiac region, or even more so; but in other cases there may be every variety of bruit.

Pressure-effects.—The most important symptoms are occasioned perhaps by the pressure-effects of the tumor upon the neighboring parts affecting the parts: the venous circulation, the nerves, respiration, and deglutition.

The **Pulse** is usually influenced, being much smaller and feebler in the radial artery of the affected than of the sound side, and in some instances being completely arrested; owing, doubtless, to pressure on or occlusion of the subclavian. The pulsation in the right carotid and its branches is also frequently much less powerful than in the opposite vessel. These signs commonly occur before any external tumor is seen or can be felt, and hence constitute an important element in the early diagnosis of the disease.

Enlargement of the Superficial Veins of the neck and right upper extremity is of frequent occurrence, the external jugular being the vessel that is usually first evidently dilated; at a more advanced period the superficial subcutaneous veins of the upper part of the right side of the chest often become tortuous and form a dense plexus in this situation, while many anastomose with the cephalic and thoracic veins above, and the superficial epigastric below. As the pressure increases, oedema commences in the right eyelids and hand, and may speedily extend to the whole of the head, face, and arm, which become hard and brawny in consequence of serous infiltration. In one instance I have seen the left arm become suddenly oedematous, the left innominate vein being pressed upon. In these cases the eyes become staring and prominent, and the lips, nose, and features livid and turgid with blood, as well as oedematous, so as to alter greatly the expression of the countenance.

Pain of a dull aching character is experienced in the situation of the tumor, from the compression of the neighboring structures. But in the later stages of the disease the patient often experiences sharp shooting pains, apparently of a rheumatic or neuralgic character, in the arm and the side of the head and face, arising from pressure upon, and irritation of, nerves of the cervical and brachial plexuses. Taking the course of the ascending and descending filaments of the cervical plexus, the pain shoots up the side of the head and neck, and over the shoulder and upper part of the chest; or, from pressure upon the brachial plexus, it radiates down the hand and arm, being usually especially severe about the elbow and fingers. The muscular power of the right arm also commonly becomes impaired. Persistent dilatation of the vessels, with sweating of one side of the face, occasionally occurs from pressure on the sympathetic.

Dyspnoea is of very common occurrence, and of very varying degrees of intensity, from slight difficulty in breathing up to fatal asphyxia. It may

Fig. 466. — Aneurism of the Innominate Artery compressing and stretching the Recurrent Laryngeal Nerve, and pushing the Trachea to the Left Side. Back View.)

proceed either from compression of the recurrent nerve, or from pressure on the trachea. When it depends on the former condition, the voice is hoarse, husky, or whispering; and there is a dry, croupy, and paroxysmal cough, usually accompanied by expectoration of thin frothy mucus. In these cases, after death, the right recurrent nerve will be found to be stretched out and greatly elongated by the pressure of the tumor (Fig. 466). Compression of the trachea, which becomes flattened and curved over to the left side by the protrusion of the tumor, is a common cause of dyspnoea, and is not unfrequently associated with pressure on the recurrent nerve.

The laryngeal dyspnoea in these cases is analogous to that which occurs in aortic aneurisms (p. 175); the only difference being, that in one case it is due to pressure upon and paralysis of the muscles supplied by the right; in the other, of those to which the left

recurrent nerve is distributed. It is the paralysis of the crico-arytenoid posterior muscle that is so especially distressing and dangerous; for by its paralysis the corresponding side of the glottis is closed. More rarely by far, the right bronchus is compressed by the extension of the tumor downwards.

Dysphagia is of sufficiently frequent occurrence, and varies from slight uneasiness in deglutition to an impossibility of swallowing anything except fluids. I have never seen it occur without having been preceded by dyspnoea; and, in every instance that has fallen under my observation, it has been associated with laryngeal dyspnoea. The coincidence of these two symptoms is readily explained by the anatomy of the parts; the recurrent nerve, lying between the sac and oesophagus, must suffer compression before the mucous canal be interfered with.

Prognosis.—The prognosis of brachio-cephalic aneurism is in the highest degree unfavorable, though the disease frequently does not run a rapid course. If it extend upwards and outwards, the tumor may acquire a very large size before any very important organ or part is implicated; but if it press backwards and inwards, it may prove fatal at an early period. I know of but one case of spontaneous cure (reported by J. Ogilvie), and but few instances in which the rupture of the sac has taken place. The most frequent cause of death is asphyxia, from spasmodic closure or paralysis of the larynx induced by pressure on the recurrent nerve; or from pressure on the trachea.

Diagnosis.—The diagnosis of innominate aneurism is usually sufficiently easy, if attention be paid to the symptoms that have just been detailed. But at times the difficulty is so great as to baffle the most sagacious Physicians and most experienced Surgeons: that which has during life been considered to be an aneurism of the innominate artery, having, after death, proved to be one of the summit of the aortic arch rising up into the root of the neck behind the right sternomastoid, or overlapping the brachio-cephalic trunk.

The task of overcoming this difficulty in diagnosis must be left to the tact of the Surgeon. But it is impossible to overestimate its importance, when the question of ligaturing the arteries at the root of the neck for a supposed innominate aneurism is contemplated; for, in at least three cases in which this operation has been done, the arch of the aorta has been found to be the seat of disease, the innominate in two of the cases being unaffected by aneurism. I am acquainted also with a fourth case, in which the operation was commenced, but was abandoned, as the subclavian could not be reached; the patient dying a few days afterwards, the aneurism was found to be aortic, rising up into the root of the neck, the innominate being sound.

TREATMENT.—There are several instances on record in which a properly conducted course of constitutional treatment has cured the patient; thus a case of Luke's was permanently cured by small and repeated bleedings, conjoined with the administration of digitalis. In connection with such treatment, distal pressure might be employed, as in a case that derived benefit from this plan in Syme's hands.

In aneurism of the innominate, the vessel is so short, and the sac so situated, that it is impossible to attempt to apply a ligature on the cardiac side of the tumor. What resource, then, does surgery offer in these cases beyond the employment of constitutional and dietetic means? It may be answered to this, that, if these measures fail in arresting the disease, our choice must lie between two alternatives; leaving the patient to his fate, or having recourse to the application of the ligature on the distal side of the tumor. On looking at the innominate artery with reference to the distal operation, we are struck by two peculiarities in the vessel, which must necessarily modify to a considerable extent not only the seat of the operation, but the principle on which it is conducted. The first peculiarity to which I allude is the shortness of the trunk, which makes it impossible to apply the ligature to the vessel itself, but renders it necessary to deligate one or both of its terminal branches. The other peculiarity is, that in no circumstances can these vessels be so ligatured as to arrest the whole of the blood sent into the artery; for, although the circulation through the carotid may be entirely stopped, yet it is impossible, from the seat and extent of the disease, to tie the subclavian at any point except beyond the scalent; hence that blood which is destined for the supply of the branches of this vessel—the vertebral, the thyroid axis, the internal mammary, and the first intercostal—must continue to be propelled into and through the sac. Three distinct modifications of the distal operation have been proposed and resorted to for the cure of aneurisms in this situation: 1, Ligature of the Subclavian alone; 2, Ligature of the Carotid alone; and, 3, Ligature of Both Vessels with an interval of greater or less extent.

1. **Ligature of the Subclavian only** (Fig. 467) has been practised by Dupuytren, Wardrop, Laugier, and Broca. Dupuytren's and Laugier's cases were soon fatal, and Broca's experienced no relief, and died in six months. In Wardrop's case the tumor diminished and the patient survived for two years. This partial success may fairly be attributed in a great measure to the accident of the carotid having been occluded by the disease. The results of this practice have certainly not been sufficiently favorable to justify the Surgeon in repeating an attempt of this kind, opposed as it is to the known principles on which the distal operation effects a cure.¹ For, supposing, as we may safely do, with Wardrop, that only one-third of the

¹ The Tables of Operations for Innominate Aneurism given in former editions have not been reproduced, as the number has so greatly increased of late years as to make it impossible to record all without occupying too much space.

blood that is sent into the innominate finds its way through the extra-scapular portion of the subclavian, the remainder being destined for its branches and the carotid in equal proportions, what fact can be adduced or principle laid down from which we can expect to obtain the cure of an aneurism in close proximity to the heart, by cutting off for a short time only so small a proportion as one-third of the supply of blood sent into it? As soon as the collateral vessels have dilated, the flow of blood through the artery will be the same as before the operation, as the supply of blood to

the upper limb is maintained by means of the anastomoses of the branches of the first and second part of the subclavian with those of the axillary artery.

2. **Ligature of the Carotid only** (Fig. 468) for innominate aneurism was first performed by Evans, in 1828. The tumor diminished for a few days after operation, but at the end of seven days inflammation of the sac set in, followed by obliteration of the arteries of the right arm and the branches of the carotid. At the end of a year tumor still existed, with constant pulsation. Next year the sac suppurated, and discharged much pus. Since that time the operation has been repeated by Mott, Aston Key, Fergusson, Hutchinson, Pirogoff, and many others, amounting in all, according to Holmes, to nineteen cases. In only one case, that operated on by Evans, does the disease appear to have been materially benefited; and in that instance the good effects can scarcely be attributed to the operation, but must rather be looked upon as the result of suppuration of the sac and consequent obliteration of the arteries of the arm and head of the affected side. Key's patient died in consequence of the left carotid becoming occluded and the brain being deprived of its proper supply of blood; and in several other cases death is referred to hemiplegia and other cerebral diseases.

3. The **Carotid and Subclavian Arteries** (Fig. 469) were tied simultaneously for the relief of innominate aneurism for the first time by Ross, in 1843, but there is some doubt as to the part of the artery to which the ligature was applied. Since that time the operation has been performed by

Durham, Holmes, McCarthy, Weir, Lane, Pollock, Stimson, Little, Langley Browne, Barwell, Bergmann, and others. According to Holmes, the total number of cases up to 1882 amounted to twenty, to which Bergmann's case must be added. In seven cases marked improvement followed the operation. Stimson's patient survived the operation twenty-one months. Four months after the operation he was suddenly attacked by left hemiplegia and aphasia, after which the tumor diminished in size rapidly. He partially recovered from the paralysis. After death the third part of the subclavian and the carotid were ascertained to be obliterated; the sac of the aneurism was about the size of a hen's egg, and communicated with the subclavian, all the branches of which, except the internal mammary (which could not be found), were patent. Little's case lived three and a half years, dying at last of pleurisy. The aneurism was practically cured, but a channel existed through it to the subclavian. Of Barwell's four cases, one died from the anæsthetic, and three were successful. One died three months after the operation of bronchitis, and the second died two years after also of bronchitis, and in both of these the disease was practically cured. The third remains well up to the present time. In Browne's and Bergmann's cases the improvement continued up to the last report. Of the fatal cases, four died from rupture of the sac, one from hemorrhage from the ligatured arteries, one from shock, one from hemorrhage from the sac, one from exhaustion, one from asphyxia, one from the anæsthetic, two from the unrelieved progress of the aneurism, and in two the cause of death was doubtful. The operation was attempted in another case by Chevers, but the subclavian vein was wounded, and the patient died in two hours.

The carotid and subclavian have also been tied consecutively at intervals varying from two years to one month, in six cases, by Fearn, Wickham, Maligne, Mott, Bickersteth, and Adams and Treves. In all cases the carotid was tied first. In Fearn's case two years elapsed between the operations, and the patient died four months after the subclavian was tied, of pleurisy. The aneurism was found to be consolidated, with the exception of a channel leading to the subclavian. In Wickham's case relief followed the ligature of the carotid, but symptoms soon returned, and the subclavian was tied about six weeks afterwards, but without effect, the patient dying in two and a half months from rupture of the sac. In Mott's case a practical cure resulted, the patient dying of phthisis three years after the second operation. In Adams and Treves's case the aneurism was consolidated, but death took place 108 days after the second operation from rupture of the sac of an aortic aneurism. In the remaining cases no benefit was derived from the operation.

A *résumé* of the cases of aneurism of the innominate, in which the operation of ligaturing one or both arteries beyond the sac has been performed, having thus been given, the question arises whether these operations, or any of them, should retain a place in surgery. This question may be examined from two points of view: 1. As to the principle on which these operations are performed; and, 2. As to their results in practice. For the success of the distal operation, it is requisite that there be no branch given off, either from the sac or between it and the ligature; or that the current of blood through the sac be at least so far diminished as to admit of the deposition of laminated fibrin in sufficient quantity to fill it up, by a process similar to that which happens in a case of aneurism treated by the Hunterian method. In order that this may be accomplished, it is certainly necessary that the greater portion of the blood passing through the sac be arrested; for, if the current that is still kept up be too free, the tumor will continue to increase, as we have seen happen in cases of inguinal aneurism in which the femoral

artery has been ligatured below the epigastric and the circumflex ilii, the current through which has been sufficient to feed the sac in such way that a cure could not be accomplished. If, therefore, but one of the vessels leading from the brachio-cephalic, as the subclavian beyond the scaleni, be tied, and but a third of the blood circulating through the main artery be arrested, are we justified in hoping that the circulation through the sac will be so influenced by the diversion of this small quantity, that the remaining two-thirds of the blood, which will still pass through for the supply of the carotid and the branches of the subclavian, will gradually deposit those fibrinous laminae by which obliteration of the tumor is to be effected? Should we not rather expect that the larger current will be too powerful to allow the formation of these layers, and will continue to distend the sac in such a way as to prevent its contraction? Surely, if the comparatively small and feeble streams of blood that pass through the epigastric and circumflex ilii, are sufficient to interfere with the cure of an inguinal aneurism after the distal ligature of the femoral, the strong current that sweeps through the carotid and the large branches springing from the subclavian, with the full force derived from close proximity to the heart, will most probably be sufficient to prevent all lamination in an aneurism of the innominate. That the arrest of the circulation through one of these vessels only is not sufficient to influence materially the growth of the aneurism, is evident likewise from what is not unfrequently observed after death in cases of this kind—one or other of the vessels being found compressed and obliterated by the pressure of the sac, or plugged by fibrin, and yet no alteration in the tumor resulting. These cases, which are tolerably numerous, would of themselves have been sufficient to prove that something more than this amount of obstruction is required, in order to effect proper stratification of fibrin in the sac; and if we turn to the result of the twenty-three cases in which either the carotid or the subclavian has been ligatured, we shall find that in one case only, that operated on by Evans, of Belper, has a cure been effected; and in this instance how was it accomplished? According to the principle on which it was attempted to be established? Certainly not; but, as will be seen by attention to the details of the case, and as has already been pointed out with much acuteness by Guthrie, by the accidental setting up of inflammation, which extended to the sac, and thus obliterated it.

In the case (that of Mrs. Denmark) in which Wardrop tied the subclavian for the cure of aneurism of the brachio-cephalic, there is some reason to doubt whether the arrest of the progress of the tumor was owing to the ligature of the subclavian artery, or whether it was not much influenced by the obstruction which existed in the carotid for nine days after the operation, during which time so abundant a deposit of laminated fibrin might have occurred as to arrest the progress of the disease for some length of time. In this case, also, Guthrie supposes it probable that the inflammation of the tumor might have led to its obliteration.

From a careful consideration of all the circumstances of the cases in which ligature of one vessel only, either subclavian or carotid, has been employed for brachio-cephalic aneurism, we are, I think, fully justified in concluding that in sixteen of the cases the fatal result was accelerated, occurring as a consequence of the ligature of the vessel; in three the progress of the disease was not materially interfered with; in two it was arrested, the patients living for twenty months and two years respectively; in one the result was uncertain, and in one case only the disease was cured. The improvement in two of the cases was the result of accidental circumstances, which were unexpected, and unconnected in any way with the principles on which the operation was undertaken. These results would not, in my opinion, justify any Surgeon in

again making an attempt to cure an innominate aneurism by the ligature of either the subclavian or the carotid artery alone, the patient having been directly killed by the operation in two-thirds of the cases. Of the remaining third, in one-half the patients recovered from the operation, but the disease ran its course as if no such procedure had been adopted; and in the remaining slender percentage of cases the improvement that took place in two, and the cure in the one solitary instance, were due to accidental circumstances unconnected with the operation, and which consequently might have developed equally if none had been performed.

We have yet to consider the operation in which both arteries are ligatured. This double operation may either be performed *with an interval between the application of the two ligatures*, sufficient for the establishment of collateral circulation; or the two vessels may be ligatured simultaneously. The former plan has been adopted in six cases; the latter in twenty-one; not a sufficient number for any safe deduction. Of the six cases in which an interval intervened between the two operations the tumor seems to have been practically cured in three, in two cases no relief was obtained, and one died directly from the operation. In the twenty-one cases in which the vessels were ligatured simultaneously, death took place directly from the operation in four; the disease was unrelieved, and terminated fatally in eight; in two the cause of death is somewhat uncertain, and in seven great benefit or a practical cure resulted. It is interesting to note that the later cases have been the most successful, and it is reasonable to hope that this is due to modern improvements in the methods of tying arteries and dressing wounds. The cases, however, are not yet sufficiently numerous or free from modifying circumstances to enable us to draw any certain inference from them: we must, therefore, revert to the principle on which this operation should be undertaken. This will differ materially, according to whether the two arteries are ligatured simultaneously, or with a sufficient interval for the reestablishment of collateral circulation.

If an interval of two years, as in the first case, or even of two and a half months, as in the second instance, be allowed to elapse between the ligature of the carotid and that of the subclavian, the operation reduces itself essentially to that of the ligature of a single artery, which, as has already been shown, is insufficient to induce those changes in the sac that are necessary for the accomplishment of a cure. If the patient survive the effect of the ligature of the carotid for a few weeks, sufficient time will have been afforded for the proximal end of the subclavian, the vertebral artery, and the thyroid axis to take upon themselves a great increase of development—the collateral circulation being carried on by them and not by the left carotid; so that, by the time that the subclavian comes to be ligatured beyond the scaleni, the sac will still continue to be traversed by a current of blood for the supply of the branches of the subclavian, dilated beyond their normal size, in consequence of the task of supplying the right side of the neck, face, head, and brain being principally thrown upon them. This current through the proximal end of the subclavian, increased as it will have been by the whole of that blood which is destined to supply the place of that which should pass by the carotid, will place the sac in nearly the same condition as it was before the ligature; and will consequently, for the reason that has already been given, be too powerful for a cure to take place in the course of its stream.

It now remains only for us to consider the *simultaneous* ligature of both vessels—an operation that has been performed for innominate aneurism twenty-one times. In reasoning upon the simultaneous ligature of the two vessels, we must consider two points—1. In what condition do we place the sac? 2. Is the danger of the patient much increased?

So far as the sac is concerned, it is impossible to place it in a better condition for the deposit of laminated fibrin; two-thirds of the blood flowing through it being arrested, and that only traversing it which is destined for the supply of the branches of the subclavian. It is by no means improbable that even this stream may yet be too large and forcible to allow the process of occlusion to take place, yet it is impossible still further to diminish it; and if the aneurism be sacculated, and project from one side of the innominate artery, particularly to its internal or mesial aspect, it is by no means impossible that it may be sufficiently removed from the stream to allow consolidation of its contents.

Does it add to the danger of the patient to ligature these two vessels simultaneously rather than separately? I think not. If the risk of a double operation is to be incurred, I cannot think that it would be positively increased by the two being performed at once, instead of at separate intervals, the whole of the vessels that serve to maintain the collateral circulation in the head and upper extremity being left without interference. And the result that has followed the limited number of these operations corroborates the justice of this opinion, for we find that the patients recovered from the operations in fifteen out of the twenty-one cases.

The result of these fifteen cases, so far as the aneurism itself was concerned, was not altogether unsatisfactory when the otherwise hopeless nature of the disease is taken into consideration. In seven the patient derived great and unmistakable benefit, and in the remaining eight there is no reason to believe that the operation hastened the progress of the case towards death. So far, then, as actual results go, it is evident that the chances are decidedly against the patient's deriving any benefit from the operation, and at the same time it must not be forgotten that aneurisms of the innominate artery have been cured by palliative and constitutional treatment. It does not seem justifiable, therefore, to resort to the distal ligature till these means have had a fair trial. If, however, rest, diet, and medical treatment fail to arrest the progress of the disease, the amount of success obtained from operative interference has been quite sufficient to encourage a repetition of it in well-selected cases.

ANEURISM OF THE CAROTID ARTERY.

Aneurismal Varix of the Carotid Artery and of the Jugular Vein, as the result of punctures and stabs in the neck, has been met with in a sufficient number of instances to establish the signs and treatment of such a condition; and an instance is related by Mackenzie, in which a communication was established between these vessels as the result of disease; but I am not acquainted with any case of *Varicose Aneurism* of these vessels having been recorded. The *Signs* of aneurismal varix in this situation present nothing peculiar; and the *Treatment* must be entirely of a hygienic character, an operative interference being likely to be attended by any but a fatal result. It is the more desirable not to interfere in these cases, as the disease does not appear to shorten life.

Spontaneous Aneurism of the Carotid is not of very unfrequent occurrence; in Crisp's table of 551 aneurisms, 25 were of the carotid; and it ranks in order of frequency between those of the abdominal aorta and of the subclavian. It occurs more frequently in the female than any other external aneurism; thus, of the 29 cases alluded to, 12 were in women, owing probably to it seldom being the result of violence, but generally arising from disease of the coats of the vessel. In Holmes's table of 337 aneurisms, 11 were of the common carotid, 10 being spontaneous, and 1 trau-

matic. Three of the former were in women. This aneurism is also remarkable as occurring at earlier stages than most others; thus, Hodgson has seen it in a girl of ten; Sykes, of Philadelphia, in one of eighteen; C. Heath, in a woman aged twenty-three (external carotid), who was suffering from extensive disease of the cardiac valves. The right carotid is much more commonly affected than the left, and the upper portion of the vessel than the lower; indeed, the bifurcation is the most common seat of aneurismal dilatation. The root of the right carotid not uncommonly is dilated; but I have never seen or heard of a case in which the left carotid, before emerging from the chest, has been affected.

SYMPTOMS.—A carotid aneurism in the early stage presents itself as a small, ovoid, smooth tumor, with distinct pulsation and bruit, and a well-circumscribed outline. It is commonly soft and compressible, diminishing in size on pressure, and expanding again with the usual aneurismal dilatation. As it increases in size, it becomes more solid, occasions shooting pains in the head and neck, and, by its pressure on the pharynx, œsophagus, and larynx, produces difficulty in deglutition and respiration; sometimes the salivary glands are much irritated. After a time, the cerebral circulation becomes interfered with, giving rise to giddiness, impaired vision of the corresponding eye, noises in the ear, and a tendency to stupor. These symptoms may be owing to compression of the jugular, to difficulty in the transmission of the blood through the tumor, or to irritation of the cervical ganglia of the sympathetic. The size that these aneurisms may attain varies greatly; usually they are confined to the space under the angle of the jaw, but not unfrequently they occupy the greater part of the side of the neck. If they be allowed to increase without interference, death may happen, either by rupture externally, or into the pharynx or œsophagus; by asphyxia, from pressure on the larynx or recurrent nerve; or by starvation from compression of the œsophagus.

Aneurisms of the carotid are usually of slow growth, and may sometimes exist for a considerable number of years without giving rise to any special inconvenience; this is more particularly the case when they are seated at the bifurcation of the artery. I have, however, seen a spontaneous aneurism in this situation attain the size of a small orange in a few weeks. When at the root of the neck, they are more likely to be attended by injurious pressure-effects at an early period.

DIAGNOSIS.—The diagnosis of carotid aneurism is without doubt more difficult than that of any other form of external aneurism; the best proof that this is so, may be found in the fact that, of the cases in which the carotid artery has been ligatured for supposed aneurism of it or its branches, in several instances no such disease existed—solid cysts, or other tumors of the neck having been mistaken for aneurism, and this by surgeons of great and acknowledged repute.

The diagnosis of aneurism of the lower part of the carotid from similar disease of other arteries at the root of the neck, as of the subclavian, vertebral, and brachio-cephalic, and the arch of the aorta, is surrounded by difficulties, which can be cleared up only by a careful stethoscopic examination

Fig. 470. Aneurism of the Summit of the Arch of the Aorta, simulating Carotid Aneurism.

of the part. In some aneurisms of the arch of the aorta, the sac rises up into the neck, so as closely to simulate a carotid aneurism, as in the annexed cut (Fig. 470); and this greatly increases the difficulty of the diagnosis. In such cases, Holmes suggests that the effect produced by carefully applied distal pressure may aid in the diagnosis. If, after a few hours, when the collateral circulation should be commencing to enlarge, the sac shows no signs of diminished tension, the case is very probably one of aortic aneurism. The principal affections of the neck, however, with which aneurism of the carotid may be confounded, are varix of the internal jugular vein, enlarged lymphatic glands, abscess, tumors, cysts in the neck, and pulsating bronchoecle.

A dilated artery doubled upon itself may closely resemble an aneurism when situated at the root of the neck. Such a case is recorded by Coulson. It occurred in woman of 88. No treatment was adopted, and after death the supposed aneurism was found to be a reduplication of the common carotid surrounded by indurated cellular tissue.

From varix the diagnosis may readily be made by attention to the following circumstances; that in varix the tumor is always soft, does not pulsate expansively, and diminishes in size during a deep inspiration, and on compressing the vein on its distal side.

Glandular tumors of the neck are often very difficult to distinguish from aneurism, more particularly when the artery passes through and is embraced by the tumor, so that the whole mass distinctly moves at each pulsation. In these cases also there may be an apparent diminution in the size of the tumor on compression, by the artery within it being emptied, or by the growth receding into some of the interspaces of the neck. But in the great majority of instances, attention to the globular, oval, and nodulated feel of glandular swellings, and the possibility of raising them up and pushing them away from the vessel—which may best be done by feeling the carotid with the ends of the fingers of one hand, and then pressing upon the tumor with the other—will clear up the true nature of the case.

From abscesses of the neck the diagnosis must be made on general principles. The coexistence of ill-defined hardness and enlargement of the glands, of an inflamed state of the skin, the ready detection of fluctuation, and the absence of expansile pulsation in the tumor, will show that it is not aneurismal, however similar its other characters may be. It is of importance to observe also that an aneurism that fluctuates is always forcibly distended with strong pulsation, and can be materially diminished by pressure, neither of which circumstances can possibly occur in abscess. But if abscess may be mistaken for aneurism, the converse also holds good; and an aneurism may, unless care be taken, be mistaken for abscess—a far more fatal error. And there is one variety of false aneurism, that to which Liston has invited special attention, against which the Surgeon must be carefully on his guard, on account of the many points of resemblance between it and aneurism; I mean the case in which an artery has given way into the sac of an abscess. In this case, fluctuation and pulsation will exist, although not perhaps of a distending kind. An important diagnostic mark will be, however, that the outline of an aneurism is distinctly defined and limited, while that of an abscess never is. Aneurism of the internal carotid has been found by Syme to simulate very closely abscess of the tonsils.

Tumors of various kinds—carcinomatous, fatty, and fibrous—may occur in the neck, and cause some little embarrassment in the diagnosis from aneurism, thus Lafranc, O'Reilly, and Kerr, of Aberdeen, have recorded cases in which the artery has been ligatured in such cases by mistake for aneurism. The diagnosis of such tumors as these must be effected on ordinary principles. I have in several instances met with a small, hard, distinctly circumscribed

tumor lying directly upon the carotid artery, and apparently connected with it, and receiving pulsation from it, usually produced by a fit of coughing or laughing. This tumor, with the true nature of which I am unacquainted, remains stationary, and does not require any operative interference.

The thyroid body is not unfrequently the seat of enlargements, that have been mistaken for aneurism. These consist chiefly in a circumscribed enlargement of one lobe of the gland, which extends laterally over the common carotid, and receives pulsation from it. This kind of bronchocele may be diagnosed from aneurism by the communicated pulsation in it ceasing when it is raised from the artery. The most puzzling cases, however, and those in which mistakes may most easily be made, are instances of *pulsating bronchocele*, in which these tumors have an active and independent pulsation or thrill. In these instances, however, there are three points that will almost invariably enable the Surgeon to effect the diagnosis. Thus the tumor, although principally confined to one lateral lobe, always affects the isthmus more or less. Then again, in bronchocele, that portion of the tumor is most firmly fixed which stretches towards the mesial line; whilst in carotid aneurism the firmest attachment is under the sterno-mastoid muscle. The third point of difference is that, on desiring the patient to make an effort at deglutition, the enlarged thyroid body moves with the larynx and trachea. *Cysts in the thyroid body* are of more common occurrence than pulsating bronchoceles, and sometimes equally difficult of diagnosis. Dupuytren has pointed out that, when these cysts are tapped, the pulsation often becomes stronger, and the fluid, which on first flowing is serous, may at last become pure arterial blood, so that the Surgeon may suspect that he has punctured an aneurism.

TREATMENT.—**Digital Compression** has of late years been successfully employed for the treatment of carotid aneurism. A case of aneurism of the common carotid artery, cured by intermittent digital compression, has been recorded by Rouge, of Lausanne. The patient was a male, aged 68. Compression was made by placing the thumb against the anterior edge of the sterno-mastoid and the next three fingers under the posterior edge of the muscle; the artery was thus seized and compressed. This avoided any pressure on the pneumogastric nerve, which was supposed to be the cause of the pain usually produced by attempts to compress the carotid. The compression was applied for seventeen days during seven or eight hours each day; and at the end of the time the man was cured. In addition to this, Holmes has collected four successful cases by Sheppard, Kerr, Humphry, and Gay, and two unsuccessful by De Castro and Delore. The pressure should, if possible, be applied above the transverse process of the sixth cervical vertebra, so as to avoid compressing the vertebral artery at the same time.

Ligature.—Since the time when Sir A. Cooper first ligatured the carotid, in 1805, the means on which the Surgeon almost always relies for the cure of aneurism of this vessel is deligation of the artery at a distance from the sac.

When the aneurism is so situated that a sufficient extent of healthy vessel exists between the sternum and the base of the tumor to admit of the application of a ligature, the Hunterian operation may be practised. If, however, the root or lower portion of the artery be so involved that there is no room to apply the ligature between the heart and the seat of the disease, the distal operation may be performed.

Ligature of the Carotid.—The patient must be placed upon his back with the shoulders supported by a pillow, and the head allowed to fall backwards so as to put the sterno-mastoid slightly on the stretch. In the later stages of the operation, the head must be brought a little more forwards to allow the muscle to be drawn outwards. If brought too much forwards the artery becomes relaxed, and the difficulty in passing the needle is increased. When

the Surgeon can choose the seat at which to ligature the artery, he usually selects the part of the vessel which bisects the angle formed by the anterior edge of the sterno-mastoid with the omo-hyoid muscle at the level of the cricoid cartilage. The course of the artery is marked by a line drawn from the sterno-clavicular articulation to a point midway between the mastoid process and the angle of the jaw. The practical guiding line during the operation is the anterior border of the sterno-mastoid, which forms the first rallying point. The artery is reached by making an incision about three inches in length in this line, the middle of the wound being opposite the cricoid cartilage. After dividing the skin, superficial fascia, and platysma, with the branches of the superficial cervical nerve, and the deep cervical fascia, the fibres of the sterno-mastoid come into view; the inner border is easily found, and the muscle turned outwards. The second rallying point is the upper border of the anterior belly of the omo-hyoid. To bring this into view, the layer of cervical fascia forming the posterior part of the sheath of the sterno-mastoid must be dissected through, taking care not to wound the descendens noni nerve, which usually lies immediately beneath it. When the muscle is found, its upper border is pushed downwards with the handle of the scalpel, and held out of the way with a blunt hook, and the sheath of the vessels then comes into view. The Surgeon now presses his finger backwards towards the bodies and transverse processes of the cervical vertebrae, and the artery will be felt rolling under the finger over the bone, and its exact position is thus easily ascertained. The vessel is enclosed in a sheath of cervical fascia common to it, the internal jugular vein, and the pneumogastric nerve. This sheath is divided into three compartments by distinct fibrous septa, and it is important to open the most internal of these, in which the artery lies, if possible without disturbing the others. To do this, the common sheath must be opened well to the tracheal side, as the compartment for the vein is much larger than that for the artery, and occupies the greater part of the anterior aspect of the sheath which is exposed in the operation. After opening the common sheath, the special sheath of areolar tissue surrounding the artery must be carefully divided until the white external coat comes into view. The needle is then passed from without inwards (Fig. 471), between the special sheath and the external coat, through the loose areolar tissue naturally found in this situation. If the vessel be properly cleaned, it is almost impossible to wound the vein or pick up the nerve. If, however, the wrong compartment of the common sheath be opened, or the special sheath not properly divided, either of these accidents may happen. Almost all the accidents which may happen in ligature of the carotid arise from one of two causes, either drifting too far outwards in the deeper part of the incision, or not cleaning the vessel sufficiently before passing the needle. In cases of aneurism the difficulty is often increased by the proximity of the sac, and sometimes by inflammatory thickening of the sheath. In females the edge of the thyroid body may overlap the artery, and present a somewhat puzzling appearance when exposed. In performing the operation subcutaneous vessels are occasionally wounded, which may bleed rather freely; if so, they should be ligatured. If the outer compartment of the sheath is accidentally opened, the jugular vein swells up so as to obscure the artery, but all difficulty from this source will cease if it be drawn aside by a retractor, or repressed by the assistant's finger. When this happens, it must not be forgotten that the proper compartment of the common sheath, and the special sheath of the artery, have both to be opened before passing the needle. The pneumogastric nerve should never be seen, as it lies deeply behind the vessels.

After the operation the patient should be propped up in bed with the head forwards, in order to prevent any strain upon the artery. Rest can be still

more perfectly obtained by applying a leather splint moulded before the operation to reach from the loins to the back of the head, and to overlap the shoulders. It can be put on immediately after the operation, and worn for the first two weeks.

Ligature of the Carotid below the Omo-hyoid becomes necessary if the aneurism have attained a very considerable size, extending low in the neck, and not leaving perhaps more than one inch of clear space above the clavicle. The operation is best performed by dividing the sternal head of the sternomastoid close to its origin. A V-shaped incision must be made, one limb of

Fig. 471.—Incision for Ligature of the Carotid Artery.

Fig. 472.—Diagram of the Right Common Carotid Artery at the seat of Ligature. *p.l.* platysma; *s.m.* sternomastoid, drawn to one side; *o.h.* omo-hyoid, drawn downwards and inwards; *s.h.* sterno-hyoid; *a.* the artery; *e.* internal jugular vein; *d.n.n.* descending noni nerve. The pneumogastric is not seen, as it lies behind the vessels.

which corresponds to the lower two inches of the inner border of the sternomastoid, and the other to the inner two inches of the clavicle. The incisions are deepened till the muscle comes into view, the inner head is then divided and turned up in the V-shaped flap. The second rallying point is the edge of the sterno-hyoid. While searching for this, care must be taken not to wound the anterior jugular vein, which crosses the muscle transversely on its way to join the external jugular. When the edge of the muscle is found, it may be drawn on one side with a spatula, or, if necessary, notched. The sterno-thyroid scarcely requires division. The sheath of the vessels now comes into view, and must be cautiously opened, the Surgeon keeping carefully to the tracheal side, so as to avoid the vein. There is usually a wide interval between the artery and the vein and nerve on the right side; on the left side more care is required, as the vein most commonly overlaps the artery.

After ligature of the common carotid, it is interesting to observe that the collateral supply is not afforded by any of the branches of the corresponding vessel of the opposite side, but by the subclavian artery of the same side. In a case related by Porter, in which the right carotid had been tied, the subclavian and vertebral arteries on the same side were enlarged to at least

double their natural diameters, and the chief communications outside the skull took place between the superior and inferior thyroid arteries, which were enlarged; whilst inside the cranium the vertebral took the place of the internal carotid. Immediately after the operation the blood may be so freely conveyed to the distal side of the vessel, by the free communication subsisting between the arteries of opposite sides, both within and without the cranium, that a continuance or a speedy return of pulsation in the sac is of common occurrence. This condition, however, usually disappears after a time by the gradual consolidation of the tumor, and indeed may generally be looked upon as a favorable sign; being very seldom associated with those cerebral symptoms that, as will immediately be explained, commonly prove fatal after this operation. Occasionally the pulsation continues, and the tumor gradually increases in size in spite of the occlusion of the main trunk.

Suppuration of the sac is not of very uncommon occurrence after the ligation of the carotid for aneurism—sometimes even after so considerable an interval as eight months, as happened in a case related by Post. In the majority of these instances, the patient eventually does well; but death may result by the tumor pressing upon the pharynx and larynx, or by the occurrence of secondary hemorrhage, which may take place either from the part to which the ligature has been applied, or from the suppurating sac. In the first instance, it usually occurs about the period of the separation of the ligature; in the second, it may happen at a considerably later period, even after many weeks. In a case under the care of H. Morris, suppuration took place round the sac fifteen weeks after the ligature was applied to the main trunk. Pus was let out by an incision, after which the tumor rapidly increased, with return of pulsation. The sac was then laid open. The aneurism was found to have sprung from the external carotid, and the recurrent stream of blood was derived entirely from the branches of that vessel. The trunk above the sac, the facial, and the superior thyroid were ligatured, and the patient made a good recovery. As the suppuration is often due in all probability to the proximity of the wound and the ligature to the aneurism, it has been suggested that, in such cases, it might be safer to anticipate it by laying open the sac after the application of the ligature on the proximal side, and tying the vessel again on the distal side, thus performing a combination of Anel's and the old operation. It would appear, however, as if this were only substituting, with certainty, one evil for another that may very possibly be avoided. Besides these, which may be looked upon as the ordinary accidents following the application of a ligature for aneurism, deligation of the carotid artery occasionally gives rise to serious and even fatal disturbance of the circulation within the cranium.

Effects on the Brain of Ligature of one or both Carotids.—Many experiments have been made by Meyer, Jobert, and others, upon the lower animals, with the view of determining the effect produced on the brain by the ligature of the carotid arteries. But the deductions from these are of no value whatever when applied to the human subject, for the simple reason (which appears to have been strangely overlooked), that in many of the lower animals on which the observations were made, as the dog and rabbit, for instance, the common carotid arteries are of secondary importance so far as the cerebral circulation is concerned, being destined principally for the supply of the external parts of the head—the brain deriving its chief supply from the vertebrals; whilst in other animals, as the horse, the brain derives nearly the whole of its blood from the carotids, and but a very small quantity from the vertebrals. Hence, in one case the carotids may be ligatured without danger, whilst in the other their dissection is inevitably fatal. The

statistics of ligature of the carotid in the human subject have been collected by Norris, Ehrmann, and others; and more recently by Pilz, of Breslau, (*Archiv für Klinische Chirurgie*, 1868), who has collected 600 cases of the operation, including 27 in which the artery was tied on both sides. The causes which led to the operation were, hemorrhage, in 228 cases; aneurism, in 87; erectile and other tumors, 142; extirpation of tumors, 71; cerebral affections (epilepsy, etc.), 34; and in 38 instances the distal operation was performed for aneurisms of the aorta and innominate artery. In the 228 cases of ligature for hemorrhage, the presence of cerebral symptoms is noted in 69 out of 167—no information being given in regard to 61; and, in these 69 cases, death took place in 40. Excluding, however, these from calculation, inasmuch as the brain disorder may have been in many due to the hemorrhage rather than to the operation, we derive from Pilz's statistics the following table showing the proportionate frequency of the occurrence of cerebral disease and of deaths from this cause.

TABLE OF LIGATURE OF CAROTID FOLLOWED BY
CEREBRAL DISEASE.

CASE OF OPERATION.	NUMBER OF CASES.	CASES IN WHICH CEREBRAL AFFECTION ENSUED.	DEATHS FROM CEREBRAL DISEASE.	DEATHS FROM ALL CAUSES.	NO RECORD REGARDING CEREBRAL SYMPTOMS.
Aneurism	87	32	16	31	5
Erectile and other Tumors	142	32	20	49	8
Extirpation of Tumors	71	13	8	25	8
Cerebral Affections.	34	8	...	1	3
Distal Operation	38	11	7	25	0
	372	96	51	131	19

By this it will be seen that the most common cause of death after ligature of the carotid is cerebral disease induced by the operation (as was, I believe, first pointed out by Chevers); and this result appears to have been relatively more frequent after the distal than after the Hunterian operation. If to these cases we add 14 in which the brachio-cephalic artery was ligatured, we get a total of 386 cases, of which 96 were attended by cerebral symptoms; or, as nearly as possible, 25 per cent.

We should necessarily expect that, in those cases in which both vessels had been ligatured, there would be a greater tendency to cerebral disturbance than in those in which only one had been deligated. It would however appear, as is shown by the following table, that of twenty-seven instances in which the double operation has been performed, death is recorded to have happened but in two cases from this cause; while in another, in which convulsions took place, a fatal result did not occur, and three other cases were attended by mere temporary disturbance of vision. In the only case (that of Mott, No. 16) in which both carotids were ligatured simultaneously, with an interval of only a few minutes between the operations, coma and death resulted.

CASES OF LIGATURE OF BOTH CAROTIDS

OPERATOR	AGE	DISEASE	DATES OF LIGATURE	RESULTS
1. DUPUTREY and ROBERT.	—	Aneurism by anastomosis of scalp.	Right carotid tied by Duputrey in 1819; left by Robert for extension of disease, in 1827.	Delirium, lamina of skull, and death.
2. MACGILL.	—	Fungous tumor of both orbits.	Interval of a month.	Recovered.
3. ULMANN.	20	Erectile tumor of orbit.	Left tied first 1822; right one year afterwards.	Death of third day by hemorrhage.
4. MURRAY.	20	Aneurism by anastomosis of scalp.	Left carotid Sept. 20; right carotid, Oct. 2, 1827.	Recovered.
5. MOLIER.	44	Erectile tumor.	Sept. 13, 1831, and Jan. 28, 1832.	Recovered.
6. PRESTON.	50	Epilepsy; Hemiplegia.	Right carotid, tied Aug. 27; left carotid Nov. 14, 1831.	Recovered.
7. PRESTON.	24	Partial paralysis and headache.	Right carotid, Sept. 7; left, Oct. 10, 1831.	Recovered.
8. PRESTON.	—	Epilepsy.	Tied at interval of month.	Recovered.
9. KÜHL.	53	Aneurism by anastomosis of scalp.	Left carotid, May 24, 1834; right on Aug. 4, same year.	Recovered; convulsions after embolization.
10. F. H. HAMILTON.	18	Epilepsy.	Right carotid, Aug. 1838; left, March, 1839.	Recovered.
11. VELPEAU.	20	Aneurism by anastomosis of both orbits.	Right carotid first, August, 1840; left, about three months afterwards.	Recovered.
12. PIROGOFF.	20	Hemorrhage from aneurism by anastomosis of scalp.	Left carotid, Jan. 16, 1843; right, Jan. 9, 1844.	Headache and vomiting after each operation; recovery.
13. ELLIS.	21	Secondary hemorrhage following gunshot wound of tongue.	Interval of four and a half days.	Cured.
14. J. M. WARREN.	25	Erectile tumor of nose.	Tied left, October 5; right, Nov. 7, 1845.	Cured.
15. ROBERT.	—	Aneurism by anastomosis of forehead.	Left on June 5, 1846; right on Feb. 22, 1847.	Headaches; temporary disturbance of vision; recovery.
16. MOTT.	—	Carcinoma of parotid.	Interval of fifteen minutes.	Cured and death in 24 hours.
17. MOTT.	—	Epilepsy.	Interval of half a year.	Recovered.
18. BLACKMAN.	15	"Fungus of nasal fossae."	Right first; left, three weeks later.	Temporary loss of vision; left eye recovered.
19. MURRAY.	19	Erectile tumors.	Left first; right, one month after.	Temporary disturbance of vision; recovery.
20. REYNOLDS and VAN BUREN.	—	Aneurism by anastomosis.	Right carotid tied by Reynolds in 1844; left by Van Buren in 1850.	Recovery.
21. PARKER.	45	Carcinoma of antrum.	Interval of thirty-two days.	Death.

CASES OF LIGATURE OF BOTH CAROTIDS—Continued.

OPERATOR.	AGE.	DISEASE.	DATES OF LIGATURE.	RESULTS.
22. WOOD.	53	Encephaloid of antrum.	Right carotid, July 18; left, Dec. 26, 1856.	After second operation the tumor diminished: then diarrhoea, rigors, delirium, exhaustion, and death on sixtieth day.
23. G. C. E. WEBER.	20	Epilepsy.	Left carotid, Dec. 2; right, Dec. 19, 1857.	Recovered.
24. CARNOCHAN.	...	Large morbid growth of face (elephantiasis).	Right carotid tied, Nov. 1858; left, June, 1859.	Cured.
25. LONGMORE.	...	Gunshot wound.	Right, May 12, 1863; left, May 18.	Death in thirty-eight hours.
26. BILLROTH.	27	Ulceration of carotid from syphilitic caries of petrous bone; Hemorrhage.	Right carotid, Dec. 13; left, Dec. 26, 1864.	Return of hemorrhage on sixteenth day: death from exhaustion: no cerebral symptoms.
27. BUENGER.	34	Aneurism by anastomosis and wound.	Left tied for the aneurism; five years afterwards the right, for a suicidal wound.	Disorganization of right eye: recovery.

After a careful examination of this subject, I think we are warranted in coming to the following conclusions. 1. Ligature of one carotid artery is followed by cerebral disturbance in more than one-fourth of the cases, above one-half which are fatal. 2. When the two carotids are ligatured *with an interval of some days or weeks*, the operation is not more frequently followed by cerebral disturbance than when only one is tied. 3. Pathological investigation has shown that, if the vessels be gradually and successively obliterated, the patient may live, although one carotid and one of the vertebral arteries have been occluded by disease and the other carotid ligatured, as in a case related by Rossi. 4. As in a case recorded by Davy, an individual may even live for a considerable time, though both carotids and both vertebrals be occluded—the cerebral circulation being maintained through the medium of the anastomoses of the inferior and superior thyroids and the deep cervical with the occipital artery. 5. The reason why more or less extensive obstruction by disease of the arteries leading to the brain may, as appears from pathological records, be unattended by cerebral disturbance, while this so frequently follows ligature, lies (as has been pointed out by Pilz), that in the former case the obstruction is gradual, so that the collateral circulation has time to be established, while in the latter the interruption is sudden.

The cause of these cerebral symptoms is certainly the disturbance of the cerebral circulation, induced by the ligature of the carotid. When a considerable portion of the supply of blood to the brain is suddenly cut off, two sets of symptoms may ensue—one *immediate*, the other *remote*. The immediate symptoms are those that generally result from functional disturbance of the brain, consequent upon too small a supply of arterial blood. They consist of syncope, trembling, twitches, giddiness, and impairment of sight.

After this condition has been maintained for a few days, the nutrition of the organ becomes materially affected, and softening of the cerebral substance takes place; giving rise to a new and more serious set of symptoms indicative of this pathological condition, such as convulsions, hemiplegia, and death. In other cases congestion may come on, either by the interference with the return of blood through the jugular vein, or as a consequence of that venous turgidity which we commonly observe after the ligation of a main arterial trunk; or perhaps coma may be induced by apoplectic effusion into a softened portion of the organ.

Effects on the Lungs.—Besides the brain, the lungs are not uncommonly secondarily affected after ligation of the carotid. To this condition special attention has been directed by Jobert and Miller. The lungs appear to become greatly congested, and this condition has a tendency to run into a subacute form of inflammation. The cause of this congestion of the lungs is extremely interesting. It cannot be owing to the simple obstruction of the passage of the blood through the carotid causing a disturbance in the balance of the circulation, and thus a tendency to internal congestion; for, if this were the cause, we ought to meet with it generally after ligation of the arteries of the first class. Nor can it be owing to any injury sustained by the eighth nerve during the deligation of the artery; as in many of the instances in which it is stated to have occurred, there was no evidence of that nerve having been exposed or damaged, and every reason, from the known skill of the operators, to believe the contrary. I am rather inclined to look upon the unusually frequent occurrence of pulmonic congestion after ligation of the carotid, as a secondary condition consequent upon a derangement in the functions of the brain and medulla oblongata, primarily induced by the disturbed state of the circulation through that organ; for we know that any cause which depresses the activity of the nervous centres tends to diminish proportionately the freedom of the respiratory movements, and thus, by interfering with the due performance of the act of respiration, disposes to congestion of the lungs, as seen in injuries of the head, in apoplexy, and in the operation of the sedative poisons. It would appear from the details of some of the recorded cases, as well as from Jobert's experiment, that blood-letting is of considerable service in the removal of this condition, and should consequently not be omitted.

Ligation of the Carotid on the Distal Side of the Sac.—Aneurism of the carotid artery, occurring low in the neck, does not admit the application of a ligation on the cardiac side of the tumor. What, then, is to be done in such a case as this? Should it be left to the remote chance of a spontaneous cure, or should it be subjected to surgical interference? Spontaneous cure in carotid aneurism has never yet, I believe, been met with. The Surgeon, therefore, must endeavor to treat the disease by ligation. Two plans of treatment are open to him—to tie either the innominate artery, or the carotid on the distal side of the tumor. The first alternative may fairly be set aside; for not only are the cases in which it is possible to find room between the sternum and the sac extremely rare, but, even were such an instance to present itself, few Surgeons would, I think, be justified in undertaking an operation which has only once succeeded, even (p. 213) in the most skillful hands; we are consequently reduced to the alternative of ligaturing the artery on the distal side of the sac. But although this operation is the only alternative that presents itself, yet its application in practice is attended by serious difficulties and perplexities; for the Surgeon must be able to satisfy himself that it is actually an aneurism of the root of the carotid with which he has to do, and that it is not the trunk of the innominate or the arch of the aorta that is affected. The difficulty in doing this is

far greater than would at first appear; for, on examining the details of eight cases in which the distal operation has been performed for supposed carotid aneurism, three must be excluded; as, after death, the tumor was found to arise from the aortic arch. In the annexed table will be found the result of seven cases, in which the carotid artery has been tied for aneurism of its root on the distal side of the sac. I have excluded an eighth case, as there is reason to believe that in it the artery was not ligatured, but a portion of the sheath accidentally tied instead—an accident, by the way, which Sédillot has witnessed, which Norris states also to have occurred at the New York Hospital, and which I have known happen to a most excellent Surgeon in the case of ligature of the femoral artery.

ANEURISMS OF ROOT OF CAROTID TREATED BY LIGATURE
ON DISTAL SIDE.

OPERATION.	SEX	AGE	RESULT.	CAUSE OF DEATH.	REMARKS.
1. WARDROP. 1826.	f.	63	Recovered.	Tumor diminished until fifth day: then inflamed, suppurated, and burst. The patient recovered, and was alive three years after operation.
2. LAMBERT. 1827.	f.	49	Successful so far as aneurism was concerned.	Hemorrhage from upper portion of artery.	Tumor diminished after operation, and became consolidated; sac filled with firm coagulum, and lower part of artery closed; ulceration into artery, just above part ligatured; vessel dilated where ligatured.
3. BUSH. 1827.	f.	36	Recovered.	Suffocation was imminent before operation; tumor rapidly diminished after ligature. Alive three weeks afterwards.
4. MONTGOMERY. 1828.	m.	30	Died.	Sac suppurated.	Aneurism of arch also. Left carotid tied.
5. COLTEN DE NOYON. 1840	f.	63	Recovered.	Tumor and pulsation diminished. Alive and well three years afterwards.
6. WOOD, J. R. 1840.			Recovered.	Aneurism cured.
7. DEMME.	m.	38	Died.	Suppuration of sac: hemorrhage.	Aneurism of arch: double aneurism of carotid.
8. LANE. 1852	m.	36	Died. 68th day.	Inflammation of lungs.	Tumor filled with layers of coagulum. Ulcerated opening communicating with apex of left lung. Left carotid tied.

On analyzing the cases in which the trunk of the common carotid has been ligatured on the distal side of an aneurism of the root of that vessel, there are several points of interest that arrest our attention. Thus we find that in every case the tumor, immediately on the ligature being tightened, underwent a considerable diminution in its bulk, with corrugation of the integuments covering it, and considerable subsidence in the force of its pulsations. In one case—that of Bush—respiration, which before the operation had been attended with great difficulty, became easy; and in two others inflammation of the sac took place; being in one (that of Wardrop) unattended by bad consequences, and in the other (Demme's case) followed by death. It is not safe to deduce any general conclusion from so small a number of cases; yet

the result of these is so uniform, that I have no hesitation in stating it as my opinion, that, whether we regard the principle on which this operation is founded, the amount of success which has hitherto attended it, the necessarily fatal result of these cases if left to themselves, or the absence of any other means that hold out a reasonable hope of benefit, the Surgeon is justified in resorting to the ligature of the trunk of the common carotid on the distal side of the sac, in cases of aneurism limited to the root of that vessel.

The trunk of the *External Carotid* is so short that it seldom becomes the seat of aneurism without involving at the same time the end of the common artery at its bifurcation. It may, however, become aneurismal. The tumor, presenting the usual signs of aneurism, will be found situated under the angle of the jaw and above the level of the cricoid cartilage. From the important nature and close proximity of the parts surrounding it, the pressure-effects are serious and early. By pressure on the hypoglossal nerve the muscles of the corresponding side of the tongue may be paralyzed, so that when protruded the tongue is turned towards the affected side. Aphonia and dysphagia have been met with as early symptoms.

The treatment consists in ligature of the common carotid above the omohyoid. After this operation it may happen that pulsation continues faintly, or speedily returns to the sac, owing to the freedom of enlarged anastomoses. It has, therefore, been proposed by Morris to ligature as well the primary branches of the external carotid—a project certainly difficult in execution and probably of doubtful utility.

ANEURISM OF THE INTERNAL CAROTID.

The *Internal Carotid Artery* may be the subject of aneurism before or after it has passed through the carotid canal and entered the cavity of the skull. The symptoms of these two classes of cases differ necessarily in almost every respect, as likewise do the termination and the susceptibility of the case to surgical interference.

Extracranial Aneurism.—When an aneurism affects the trunk of the internal carotid before its entrance into the skull, the symptoms presented by this disease do not materially differ from those of aneurism at the bifurcation, or of the upper part of the common carotid, except in one important respect, which was, I believe, first pointed out by Porter, of Dublin—viz, the tendency of the tumor to extend inwards towards the pharynx, and to protrude into that cavity. The reason of this is obvious; when we consider the anatomical relations of the internal carotid artery, we at once see that its pharyngeal aspect is that which, if one may so term it, is the most superficial, and that between it and the surface the smallest amount of soft parts intervenes—nothing lying between the vessel and the mucous membrane except the thin paper-like constrictor, some lax areolar tissue, and the superior laryngeal nerve; whilst externally there are interposed between it and the integument the layers of the cervical fascia, the margin of the sterno-mastoid, the digastric stylo-hyoid and stylo-pharyngeus, and the styloid process, and above the digastric the parotid gland.

When, therefore, dilatation of the vessel takes place, it necessarily has a tendency to push forwards that part of its covering where it meets with least resistance; and, this being to the pharyngeal side, more or less prominence will consequently be found in this cavity. In a case that occurred to Syme, this was especially well marked, the aneurism of the internal carotid simulating closely an abscess of the tonsil. In two cases related by Porter in the seventeenth volume of the *Dublin Journal of Medical Science*, this was one of the most marked features, the "appearances of the tumor (as seen

by the mouth) were most alarming; the pulsation could be distinctly seen, and the blood almost felt under the mucous membrane; it seemed ready to give way and burst into the mouth every moment."

TREATMENT.—The treatment of these cases does not differ from that of aneurisms connected with the carotid arteries, and seated at the upper part of the neck; but we are not in possession of a sufficient number of facts to enable us to determine with any degree of precision what the result of surgical interference in them is likely to be. If we could give an opinion from the limited number of cases at present before the profession, we should feel disposed not to entertain a very favorable opinion of the result of the Hunterian operation, as applied to aneurism of the internal carotid outside the skull. This is doubtless owing to the situation of the aneurism against the mucous membrane of the mouth, being such that the surrounding tissues do not exercise a sufficient amount of pressure against the sac after the ligature of the vessel to allow the efficient deposition of lamellated coagulum, and consequent occlusion of the artery leading into it, which, in accordance with the principles that have been laid down in speaking of the Hunterian operation, are necessary to success.

INTRACRANIAL ANEURISM.

Aneurisms within the skull may arise from any of the arteries that are met with in this situation, though some are much more liable than others to the occurrence of this disease. Of 62 cases noted by Sir W. Gull, the basilar artery was the seat of disease in 20 cases, and the middle cerebral in 15. In 8 of the remaining cases, the internal carotid was affected as it lay by the sella Turcica; and in 6 others the anterior cerebral artery was the seat of aneurism. The vertebral arteries and their branches were affected in 28 cases, and the carotids and their branches in 34.

CAUSES.—The causes of intracranial aneurism are very obscure. It might be supposed that the comparatively small diameter of the arteries within the skull would render them little liable to the occurrence of spontaneous aneurism, were it not that the anatomical characters and physiological relations of these vessels predispose considerably to the occurrence of this affection: there being no other set of arteries in the body of the same size as those within the skull in which spontaneous aneurism so frequently occurs. This can be accounted for only by the thinness of their coats and want of an external fibrous sheath rendering them unable to support the increased tension, to which they are occasionally subjected in consequence of the alteration in pressure of the cerebral circulation at different periods, the result of some variation in the relative quantities of the different fluids within the skull, or of determination of blood to the brain. This would be the case more particularly if their natural elasticity had already been impaired by the occurrence of degeneration of their coats. As these changes are the natural consequences of advance in age, we shall find the tendency to the occurrence of this disease increases with advancing years. Thus, according to Sir William Gull, of 58 cases in which the patient's age is given, only 12 cases occurred in persons under twenty-five, five of the patients being under twenty; of the remaining 46 cases, 13 occurred in persons under forty; of the remaining 33, 29 were met with between forty and sixty, and 4 in persons above sixty. Of the 58 cases, 35 were males, and 23 females. Church believes that, in the young, intracranial aneurism is due to embolism.

The immediate exciting cause of the disease is most commonly involved in obscurity; sometimes it may be traced to a blow on the head, to a fall or concussion, or to excess in drinking; but more frequently the symptoms

manifest themselves suddenly, without being in any way attributable to such external influences, and occur in vigorous and apparently healthy persons.

PATHOLOGY.—Intracranial aneurisms are almost always formed by the uniform dilatation of the whole of the calibre of the artery—the sacculated variety being rarely met with. In the museum of University College there are, however, two specimens of sacculated aneurisms of the cerebral arteries. The coats of the arteries in this situation being very thin, and unprovided with any external fibrous sheath that would support the impetus of the blood, rupture of the vessel would occur rather than partial dilatation, if one portion only of the circumference were diseased. Occasionally, the dilatation is fusiform, extending over some length of the artery; this form is probably confined to the basilar artery (Fig. 473).

The disease would appear to be of slow growth, and the sac sometimes becomes filled with laminated coagula so completely as to occlude the orifice of the artery from which it springs.

Fig. 473. Fusiform Aneurism of Basilar Artery laid open.

The size that aneurism in this situation attains before death results is sometimes considerable; thus, in a case of aneurism of the basilar artery, that occurred some years ago at University College Hospital, the tumor was nearly as large as a walnut; in another case, in the same hospital, it somewhat exceeded this size. R. W. Smith, in the *Dublin Journal of Medical Science*, vol. xxv., mentions a case of multilocular aneurism of the left posterior cerebral artery as large as a small apple; and Serres, one as large as a hen's egg. On the other hand, they occasionally prove fatal by rupture whilst still of very small size—not larger than a pea or a nut.

It is seldom that more than one of the arteries of the brain suffer aneurismal dilatation. In the Museum of the College of Surgeons, however, are preparations (Nos. 1687 and 1688) of aneurismal dilatation of both internal carotid arteries, resembling "two bulbs about five-eighths of an inch in diameter, filling up the hollow on each side the sella Turcica, which were evidently dilatations of the carotid arteries; and from their being filled with laminae of coagulated blood, there could be little doubt of their being aneurisms of these arteries. The one on the left side was the largest; that on the right side communicated with the cavity of the artery, which was not the case with the other."

A case occurred in University College Hospital many years ago, under the care of A. T. Thomson, in which a somewhat similar condition existed. A man, forty-nine years of age, had fallen on his head some months before admission into the hospital. Since then he had been garrulous, silly, and very irritable—becoming readily intoxicated. He suddenly became comatose, with vomiting and laborious breathing; he could close both eyes, but the right pupil was dilated; the left side was paralyzed. He was treated for apoplexy, and became slightly better, but died in ten days from the first attack. On examination, an aneurism a little larger than a hazelnut was found on the trunk of the right carotid, where it gave off the middle cerebral artery, and another small one on the course of that artery. There was a globular aneurism on the corresponding artery of the opposite side; the

basilar artery was thickened, white, and opaque, as were also the other larger arteries of the brain; there was softening of both anterior cerebral lobes, especially the right one.

The arteries of the brain are very commonly healthy in these cases. Out of four instances of intracranial aneurism that have fallen under my observation, the other vessels of the brain have been healthy in three cases, and atheromatous in but one. In one case I have seen aneurism within the skull associated with aneurism elsewhere—in the thoracic aorta.

PRESSURE-EFFECTS.—The pressure exercised by an aneurismal sac situated within the skull is always chiefly directed against the yielding cerebral substance, which is often extensively disorganized. The bones of the skull, however close their proximity to the sac may be, frequently escape, and seldom suffer much. This peculiarity in the effects of aneurism in this situation may be partly owing to the very dense and compact character of the inner layer of the skull, but is doubtless principally due to the very soft and yielding nature of the contents of the cavity. Absorption of the subjacent bone, however, sometimes takes place to a limited extent; thus in one case (Moore's) the body of the sphenoid bone was indented and partially absorbed.

The parts compressed in each case will vary according to the situation of the tumor. But the structures that principally suffer are necessarily those seated at the base of the brain, and forming the floor of the lateral ventricles. In Moore's case, one of the optic nerves was flattened by the pressure of the substance of the anterior lobe; the lamina perforata, the roots of the olfactory tract, the anterior part of the corpus striatum, and a considerable quantity of the neighboring white matter of the anterior lobe, were removed. In a case recorded by Lager, the portio dura of the right side was paralyzed from this cause. In R. W. Smith's case, the floor of the third ventricle, the tuber cinereum, and the origins of the optic and olfactory nerves, suffered; the optic nerve of the opposite side was flattened and softened.

Besides the changes that take place in the cerebral substance as the result of pressure, important lesions may be met with as the effect of the interruption which the presence of the aneurism offers to the circulation in and nutrition of the cerebral hemispheres. Thus, in the case of aneurism of both internal carotids that has already been referred to as occurring at University College Hospital, there was white softening of both the anterior cerebral lobes; and this lesion was most marked on the side that corresponded to the largest aneurism, and where consequently, it may be supposed, the greatest amount of obstruction to the circulation existed.

SYMPTOMS.—The symptoms of aneurism within the skull are extremely equivocal; and, indeed, aneurism of large size may exist at the base of the brain without occasioning any symptoms whatever. An interesting instance of this occurred at University College Hospital in 1848. A man, thirty-seven years of age, died of pulmonary apoplexy and chronic pneumonia of the left lung, consequent upon the pressure of an aneurism of the commencement of the descending aorta on the pulmonary veins of that side. On examining the head after death, an aneurism of the basilar artery as large as a hazelnut was met with, of which no suspicion had been entertained during life, there having been no head symptoms whatever; the sac of the aneurism was very thin, and there was much atheromatous degeneration in the vertebral arteries.

The only symptoms that are of constant occurrence, when this disease goes on to a fatal termination, are those of hemiplegia and apoplexy. These may come on suddenly without any previous warning; or they may be preceded

by a train of phenomena indicative of the existence of chronic disease within the cranial cavity.

The most constant of these phenomena is pain: which affects, however, great variety, both in extent and character. It may be diffused, or may occupy a fixed point; it may be continuous or intermitting; it may be increased by movement, or accompanied by peculiar sensations, as of pulsation or of opening and shutting the top of the cranium.

The sight and hearing are often impaired. Dimness of sight, dilatation of one or both pupils, photophobia, diplopia, and loss of vision have been noticed in several of the cases recorded. Gowers states that intracranial aneurisms even of large size are not, as a rule, accompanied by any associated ocular changes. Nor do they often cause consecutive changes, unless their position is such as to press upon the optic nerves; there is then loss of vision with atrophy of the nerve recognizable by the ophthalmoscope. If the aneurism press on the cavernous sinus, there may be some fullness of the retinal veins, but this is usually only temporary, the pressure being relieved by the free communication between the ophthalmic and facial veins. Optic neuritis is rare as the result of intracranial aneurisms. Ptosis has been met with from pressure on the third nerve by aneurism of the posterior communicating artery. Buzzing noises in the ears, and deafness, are not uncommon symptoms; deafness, more particularly, appears to be a phenomenon of frequent occurrence.

The patient rarely loses the power of articulation and of deglutition; impairment of these functions, however, has been met with.

There may be paralysis of the side of the face, shaking palsy, or complete hemiplegia; or fits of an epileptic nature may occur. The mental condition may undergo changes indicative of chronic disease of the brain. There may be depression of spirits, listlessness, or, as was noticed in the case above related, the temper may become irritable, and the patient be garrulous or silly. Insanity has been noticed in one case. As is always the case in cerebral affections, the gastric functions are often impaired.

In some cases the presence of aneurism has been detected by a loud rough or "whizzing" noise heard on the application of a stethoscope over one side of the head, and, perhaps, audible to the patient. This sign, however, exists in but few cases; but when it does occur, it is unquestionably the most pathognomonic of all. I am not aware that it has been met with in any form of cerebral disease except intracranial aneurism.

Thus it will be seen by a reference to this list of symptoms that, with the exception of the whizzing noise, no special signs are afforded by aneurisms within the skull, which will enable us to distinguish between the symptoms occasioned by their presence and those of other tumors of the brain, and of organic cerebral disease.

Very frequently no premonitory symptoms manifest themselves; the patient being suddenly seized when apparently in good health, with apoplexy, which terminates rapidly in death.

CAUSES OF DEATH.—The fatal termination may occur from one of four causes.

1. The tumor may exercise such pressure upon the whole cerebral mass as to occasion death. This mode of termination is rare. I am acquainted with one case of this description, which is reported by Roschenberger. The symptoms were very remarkable, consisting of complete hemiplegia of the left side, with involuntary antero-posterior vibration of the head and body, and paralysis agitata of the right leg. The patient slept heavily, with loud snoring; he ate voraciously, but occasionally had considerable difficulty in deglutition and articulation; his intellect was clear, but very slow. After death, an aneu-

trum of the basilar artery as large as a pigeon's egg, containing an irregular, very hard, dry clot of blood was found pressing on the pons Varolii. The sac had given way at one point, extravasation taking place into the substance of the pons, which was softened, and of a bluish color.

2. The most frequent mode in which death takes place in these cases is by the sudden rupture of the sac and extravasation of blood into the cavity of the arachnoid and the meshes of the pia mater at the base of the brain, or into the lateral ventricles—either from the aneurism projecting into them and there giving way, or rupturing into these cavities by breaking down the intervening cerebral substance (Figs. 474, 475). When this mode of termi-

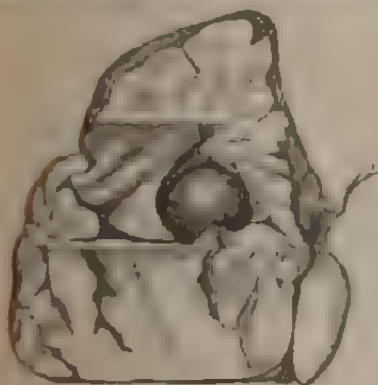

Fig. 474.—Aneurism of the Left Internal Carotid, bursting into Lateral Ventricle. View of Aneurism from above, projecting into Ventricle.

Fig. 475.—View of the same Aneurism from below, embedded in substance of Hemisphere.

nation occurs, there are occasionally no warning or premonitory symptoms of impending danger; the patient, when apparently in good health, being struck down by an attack of apoplexy, which is speedily fatal. More frequently a series of those symptoms that have already been mentioned as attending many cases of this disease, precede the fatal event for a longer or shorter time. When rupture of the sac and extravasation of blood take place, death is inevitable; at least, I am not acquainted with any case in which the appearance found after death converted me to the belief that the patient had even temporarily recovered from this condition.

Death from rupture of the sac appears to be most frequent in younger subjects. In the later period of life, aneurism is commonly associated with atheromatous disease of the vessels generally, which may cause death by softening and effusion of blood. According to Gull, of 20 cases occurring in persons under thirty-five years of age, 16 (or 80 per cent) were fatal from rupture of the sac; while in 37 cases over thirty-five, death occurred from this cause in only 14, or 38 per cent.

3. Death may result from another cause than the pressure of the aneurismal sac or its rupture and the extravasation of its contents, viz., from softening of the substance of the brain to a greater or less extent, in consequence of the obstruction offered to the passage of the blood through the aneurismal vessel. In the case of aneurism of both carotids, already mentioned as having occurred at University College Hospital, this was the case; both anterior cerebral lobes were affected with white softening, and this condition was especially observable on that side on which the aneurism was larger.

4. Lastly, death may be produced by the mere irritation occasioned by the pressure of one or more aneurismal tumors within the cranium. Of this an interesting example is afforded by the history of a case of aneurism of both internal carotids, contained in the Museum of the College of Surgeons, and related by Sir G. Blane in the *Transactions of the Society for the Improvement of Medical and Chirurgical Knowledge*, vol. ii. p. 192. In this case the patient, a lady aged 69, had suffered for four years from attacks of giddiness, headache, and imperfect vision; about sixteen months before her death she became insane, recovered, and then relapsed twice into the same state. After having regained her senses for some months, she became affected with giddiness, redness of the eyes, and violent maniacal delirium, which, continuing for some weeks, caused her death.

After death the following appearances were found: "Upon examining the body, there was no appearance in the brain itself that could in any way account for the symptoms. There was, indeed, a greater quantity of fluid than common in the ventricles, and the surface of it was moister than it is usually found in a sound state; but in all other cases which have occurred to me of organic affections of the brain proving fatal, except those which are sudden, such as apoplexy, there has been a preternatural quantity of fluid in its ventricles. There were also spicula of bone in the membrane forming the falx. The inner substance of the crura cerebri was of a brown color, and more tender than natural. The optic nerves were smaller than natural, as if they had been wasted. The septum lucidum was more than usually dense.

"But the morbid appearance in this case, which was so singular, and to which the symptoms of complaint seemed chiefly referable, was two bulbs, about five-eighths of an inch in diameter, filling up the hollow on each side of the sella Turcica, which were evidently dilatations of the carotid arteries, and, from their being filled with laminae of coagulated blood, there could be no doubt of their being aneurisms of these arteries. The dissection was made by Mr. Hunter, assisted by Mr. Home, in the presence of Dr. Jenner and myself, and all concurred in the opinion that these tumors were aneurisms. The one on the left side was the largest. That on the right side communicated with the cavity of the artery, which was not the case with the other."

TREATMENT.—In the treatment of intracranial aneurism there is usually little to be done, the nature of the case not being sufficiently obvious in the majority of instances to justify active measures. Should, however, the loud, rough whiz be distinctly audible over one side of the head, more especially about the base of the skull, or by application of the stethoscope to the mastoid process, and should symptoms of cerebral compression begin to manifest themselves, ligature of the carotid artery on the affected side may with propriety be practised. This has been done successfully in a most interesting and instructive case of intracranial aneurism by Coe, of Bristol; and unsuccessfully in one at University College Hospital, by Berkeley Hill, in which death took place from hemorrhage from the seat of ligature.

INTRAORBITAL ANEURISM.

"Intraorbital Aneurisms" were for a long time considered by Surgeons to be of the nature of erectile tumors, but the error of this opinion was pointed out by Busk, and subsequently by Nunneley, who conclusively showed that except in those very rare cases in which a pulsating tumor of the orbit is congenital, or has appeared shortly after birth, or is associated with nevusoid tissue developed in the eyelids, it must be looked upon as being due in the

vast majority of cases to the presence of an aneurism or aneurismal varix at the back of the orbit. These views have been fully confirmed by Rivington in his exhaustive paper founded on 73 recorded cases of pulsating tumor of the orbit collected from various sources, and including one very interesting case of his own. The vessel affected appears to be in some instances the ophthalmic artery itself; in other instances it would appear that the tumor is developed within the cranium, springing from the carotid artery, the ophthalmic being but secondarily affected. Delens, of Paris, has recorded three cases verified by post-mortem examination, in which the symptoms arise from an arterio-venous aneurism affecting the carotid artery in the cavernous sinus.

CAUSES.—The causes of intraorbital aneurism are in some cases very obscure; in others, it evidently and directly has originated from a blow upon the head. In the first class of cases, where the disease has been of spontaneous origin, the patient has suddenly felt a crack or snap in the orbit, like the "crack of a whip," or the "snap of a gun," and the disease has then developed gradually. In the traumatic cases, the blow upon the head has usually been severe, attended in some instances with symptoms of fracture of the anterior part of the base of the skull. In several cases it has arisen from penetrating wounds of the orbit, as from sticks or small shot.

Of the 73 cases collected by Rivington, 32 were idiopathic and 41 traumatic. Of the idiopathic cases two were congenital, probably genuine specimens of circoid aneurism; the mean age of the rest was 43, the oldest being 69. The mean age of the traumatic cases was between 30 and 31, the extremes being 11 and 72. The spontaneous cases were most commonly in women: thus, of 30 cases in which the sex is recorded, 21 were females. The traumatic form is most common in men, the number being 31 males to 10 females. Amongst the idiopathic cases, 15 occurred on the right side, 13 on the left, and 2 on both sides; of 40 traumatic cases, 10 were on the right, 27 on the left, and 3 on both.

SYMPTOMS.—The first sensation experienced is, in spontaneous cases, that of a loud snap or crack in the orbit or head. This is followed by congestion of the conjunctiva, difficulty in opening the eyelids, a feeling of tension, and in some instances severe pain in and around the orbit. Loud whizzing, rattling noises are experienced in the head, and are much increased on stooping or lying down. In traumatic cases, a persistence of congestion of the conjunctiva with redness and some oedema of the eyelids, and the occurrence of noises in the head, are usually the first indications of the mischief that has occurred. In all cases, after a time, the eyeball becomes unduly prominent, and pulsation of a thrilling vibratory character can be felt in the orbit: on the application of the ear, a loud whizzing bruit is discernible, which extends widely over the side of the head. The eyeball itself eventually falls into a state of chronic congestion; chemosis occurs, the cornea becomes opalescent, the aqueous humor turbid, and sight is impaired or lost. The bruit and pulsation are diminished or cease on compressing the carotid artery of the side affected.

PROGNOSIS.—I think it is still doubtful what would happen in a large number of these cases, if the disease were left to itself without operation. It might be supposed that it would probably have a fatal termination; that rupture would take place either into the cranial cavity or externally, and that sudden death would occur. That this has occasionally taken place is proved by recorded cases, but it is by no means a necessary consequence of the disease. I was consulted at the end of 1865 by a gentleman about 44 years of age, who, in consequence of a fall on the head a few months previously, had been attacked with symptoms of aneurism of the left orbit in the

most marked manner. The bruit and the pulsation were very loud and distinct. The eyeball was greatly protruded, the conjunctiva and eyelids were congested and swollen. Greaves, of Burton, with whom I saw the case, agreed with me in urging ligature of the carotid artery as the only means of cure. To this the patient would not consent, and preferred taking his chance. By attention to habits of life, abstinence from stimulants, and ordinary medical treatment, the tumor subsided, the eye retreated within the orbit, and the symptoms diminished greatly; so that, at the end of fourteen months from the time when I first saw him, I understand that they had to a very great extent disappeared.

But there is reason to believe that all the signs of intraorbital aneurism may entirely disappear, the disease undergoing a spontaneous cure. Collard relates the case of a man 41 years of age, who, in consequence of a fall on the back of his head by which he was rendered insensible, was gradually seized with symptoms of aneurism of the left orbit; bruit, pulsation, diplopia, and protrusion of the eyeball, together with congestion of the eyelids, being most marked. After the disease had continued for a considerable length of time, the patient was put upon a course of purgatives, with a calomel and belladonna pill daily, and cold lotions to the forehead. Under this treatment the symptoms gradually subsided, and in three years and a half from the commencement of the disease had entirely disappeared. Collard believes that in this case there was a dilatation of the ophthalmic artery and its branches, arising from and maintained by a morbid state of the ophthalmic ganglion, which furnishes vaso-motor filaments to the arteries of the eye. This ganglion he believes to have been injured by *contre-coup*, and to have remained in an abnormal state, which produced dilatation of the wall of the ophthalmic artery and its branches, increase of the pulsations and the other symptoms which have been described above. It is evident from these cases that a grave prognosis should not be hastily given, as it is only by watching the case that a correct conclusion can be arrived at. If the protrusion of the eyeball continues to increase, and the globe itself begins to suffer, and vision is lost, the prognosis becomes grave and the case is one requiring surgical treatment. If there is no increase of the symptoms after some months' observation, the patient may be left to nature unless the annoyance of the disease is so great that an attempt to give relief becomes necessary.

PATHOLOGY.—The essential features of so-called intraorbital aneurism or pulsating tumor of the orbit, may arise from more than one pathological condition. Rivington has collected 12 fatal cases in which the diseased parts were examined after death. In one only (Guthrie) was an aneurism found in the orbit. In this case the disease was double, and there was a circumscribed aneurism on each ophthalmic artery. In three cases no arterial disease was found: in one of these (Ettingen), there was obliteration of some of the veins of the orbit from old inflammatory mischief, in the other two (Bowman and Aubrey) there was obstruction to the passage of blood from the orbit through thrombosis of the intracranial sinuses. In one (Nunneley) there was a circumscribed aneurism of the ophthalmic artery before it entered the orbit; in three (Baron, Gendrin, and Nunneley) rupture of an aneurismal internal carotid into the cavernous sinus was found; in one (Wecker) simple dilatation of the carotid in the cavernous sinus was the cause of the disease, and in the remaining three, recorded by Delens, an aneurismal varix of the carotid artery and cavernous sinus was found. These three were all the result of injury, one arising from a direct wound from the point of an umbrella thrust into the opposite orbit, and the other two from severe blows on the head, probably accompanied by fracture. No case of aneurism by anastomosis of the orbit has been demonstrated by post-

mortem examination, but there is strong reason to believe that two cases which have been recorded of congenital origin were of this nature. The earlier observers supposed all cases to be due to aneurism by anastomosis. The fallacy of this opinion was first pointed out by Busk, who referred the symptoms to a rupture of the ophthalmic artery and the development of a circumscribed traumatic aneurism of that vessel; this also has not been demonstrated by post-mortem observation. Nunneley doubted the correctness of this view, and referred the symptoms, in some cases, to a peculiar vascular condition of the parts, dependent more upon an affection of the veins than the arteries, and somewhat analogous to what takes place in the exophthalmos of bronchocele. He pointed out also that in other cases an aneurism exists, but that it is not in the orbit, but behind it in the cavernous sinus. In these latter cases he showed that the prominence of the eyeball is due to distention of the veins of the orbit from obstruction to the return of blood, and the pulsation is communicated to these distended veins by the aneurism in the cavernous sinus. This view is fully confirmed by the post-mortem records quoted above. In those cases in which nothing beyond obstruction to the return of blood through the cavernous sinus and consequent dilatation of the orbital veins has been found, the cause of the pulsation is not so evident. In other cases, it is perhaps possible that some derangement of the vaso-motor influence of the sympathetic may really occasion the symptoms of increased vascular activity that are so characteristic of the disease.

The secondary phenomena that are observed in these cases, such as congestion of the eyelids, of the palpebral and ocular conjunctivæ, amounting even to chemosis in many cases, and the muddiness of the aqueous humor and lens, are doubtless due to an interference with the return of blood from these parts through the ophthalmic vein, to the consequent congestion of the smaller vessels, and to effusion of serum into the subconjunctival areolar tissue. The protrusion of the eyeball is due to the vascular tumor, whatever its precise nature may be, and the derangement in vision to an alteration in the axis of the eye consequent on this extrusion. It is remarkable that the *bruit* in these cases should be so loud, not only to the patient's own senses, but to the ear of the Surgeon; and this can be accounted for only by the proximity of the cranial bones, which may act as conductors of sound.

DIAGNOSIS.—The *Diagnosis* of pulsating tumor is sufficiently easy, but it is just as difficult to determine accurately the cause of the disease. It is probable that nearly all the traumatic cases are due to aneurismal varix of the carotid artery and cavernous sinus. The sudden onset of the disease, with a crack or snap in idiopathic cases, would lead to a presumption that a small aneurism of the carotid had given way into the sinus. Congenital cases are probably aneurisms by anastomosis. Beyond this, accurate diagnosis of the pathological condition is hardly possible. The disease most likely to be mistaken for an intraorbital aneurism is a pulsating sarcoma of the bones of the orbit. In this, however, the pulsation is less expansile and the peculiar, harsh *bruit* is wanting.

TREATMENT.—The results of the cases that have been referred to above, the uncertainty in which we often are as to the real pathology of this disease, and the certainty that in some instances at least there is no true aneurismal tumor, would justify the Surgeon in having recourse to medical treatment, aided by digital compression of the carotid, and, perhaps, the application of ice to the forehead, before proceeding to operate. That these means are occasionally successful there can be no doubt. Gioppi, of Padua, has recorded a case in which an intraorbital aneurism of great severity was cured by intermittent digital compression. The compression was kept up

for periods of a minute or two with frequent intervals; pressure continued for more than one minute caused fainting. It was cured in four days. Vanzetti and Scarramuzza have published another case, in which intermittent digital compression was kept up for five minutes at a time. The case was completely cured at the end of compression during seven hours and twenty minutes, spread over eighteen days.

Rivington has collected 16 cases, including those just mentioned, in which digital compression has been adopted. Of these, 5 were idiopathic and 11 traumatic. Two idiopathic and one traumatic were cured, in the rest no benefit resulted from the treatment. Instrumental compression has been tried in four cases without result. Galvanopuncture has been tried twice, once it failed and once it was fatal. Coagulating injections have been used four times. In all the disease was traumatic. The substance used was perchloride of iron in three cases, two of which were cured and one denied no benefit. In the fourth case a solution of lactate of iron was injected and the patient was cured. In spite of this success the injection of coagulating fluids into a dilated vein in which it is impossible temporarily to arrest the flow of blood, can hardly be regarded as a safe proceeding. When medical treatment and compression have failed in producing a decided impression, the only course left for the successful treatment of the disease is the application of a ligature to the common carotid of the side affected. This operation has been highly successful. Rivington has collected 44 cases in which it has been performed, 18 idiopathic and 26 traumatic. Of the idiopathic cases 3 died and 15 recovered; of these 15, 12 were cured, in 8 vision was restored, in 3 it was not regained, and in 1 the effect in this respect is not mentioned. The remaining 3 cases were benefited by the operation. Of the 26 traumatic cases, 3 died and 23 recovered. Of the 23, 14 were cured, 1 by subsequent injection. Vision was not regained in 4. In 5 the operation failed, 2 of these were subsequently cured by ligature of the opposite artery. Four were partially cured and one relapsed after apparent cure.

In a very interesting case which I saw in Velpeau's wards in 1839, both orbits were affected; and, as pressure on the right carotid arrested the pulsation and bruit in both, that artery was tied. But though the disease was cured in the left orbit by this operation, and temporarily arrested in the right, it reappeared in the latter situation, and was eventually cured here by the ligature of the left carotid.

ANEURISM OF THE SUBCLAVIAN ARTERY

Aneurisms of the Subclavian occur in order of frequency between those of the carotid and of the brachio-cephalic arteries. They are most frequently met with on the right side, in the proportion of about three to one; and this would appear to be in a great measure dependent on their being occasioned by direct violence, or by repeated or prolonged exertion of the arm; thus they commonly occur from falls, blows upon the shoulder, or excessive fatigue of this extremity. From the fact of the aneurisms arising from external violence, we should expect to meet with them most frequently in males, and this we do in a remarkable manner. Of 120 cases collected by Poland, only 11 occurred in females, and in 4 of these instances the disease resulted from injury; in 2 cases, both arteries were affected. The disease may be seated in any part of the vessel on the right side, though most commonly it is not dilated until after it has passed beyond the anterior scalenus. On the left side aneurism never occurs before the artery has emerged from the thorax; and then, as on the right, it most commonly happens in the third part of the course of the vessel. Subclavian aneurism may occur at any age above 21.

It is most common in middle life; and, according to Poland, is three times more frequent in England than in any other country.

SYMPTOMS.—An aneurism of the subclavian artery is characterized by a pulsating compressible tumor of an elongated or ovoid shape, situated at the base of the posterior inferior triangle of the neck, immediately above the clavicle. If it be small, it will disappear behind this bone on the shoulder being raised, so it increases in size, it fills up the whole of the space between the clavicle and the trapezius, often attaining a very considerable bulk. In consequence of the pressure which it exercises on the brachial plexus of nerves there is pain, often attended by numbness, and extending down the arm and fingers, usually with some weakness of these parts. In some instances there is a spasmodic affection of the diaphragm, owing to irritation of the phrenic nerve. The external jugular vein is commonly distended and varicose, oedema of the hand and arm may be present. The tumor does not increase rapidly in size, owing to its being tightly compressed by the surrounding parts; and, as the disease never extends inwards, it does not interfere with the trachea or œsophagus. In some cases it has been known to extend downwards and backwards, so as to implicate the pleura and the summit of the lung.

DIAGNOSIS.—The diagnosis of subclavian aneurism is usually easy, and presents no point of a special character. Mayo, however, mentions a case in which an exostosis of the first rib pushed forward the subclavian artery in such a way as to cause it to simulate an aneurism, and eventually to arrest the pulsation in it.

RISULTS.—As a subclavian aneurism increases in size, it may become diffused, and burst either externally or into the pleural sac. A spontaneous cure has more frequently occurred in this than in any other external aneurism.

TREATMENT.—The treatment of subclavian aneurism is in the highest degree unsatisfactory. *Compression on the cardiac side* can be employed only when the artery is so irregularly distributed that it rises sufficiently high in the neck to admit of pressure being applied between the scalenus and the sac. Such a combination of irregular anatomical distributions with aneurism must of necessity be excessively rare; but in one case in which it occurred, Poland succeeded in effecting a cure by digital compression, kept up for twenty-six hours. The tumor then was smaller and harder, but still pulsated. The patient left the Hospital, and, at the end of a month, the tumor was found to have become solid, and to have ceased to pulsate. The number of cases in which compression is possible, may perhaps be increased by performing the operation under prolonged anesthesia.

Direct Pressure on the sac has succeeded. It has been tried in three cases, and failed successfully. Warren, of Boston, made the pressure by means of a weight; and Corner, of Papiar, by means of a leathern cup moulded to the swelling. The attempts at obtaining consolidation of the tumor by constitutional means or by *galvano-puncture*, have hitherto failed, except in some very rare instances. A case is reported by Yeatman of the cure of subclavian aneurism by Valsalva's plan in eighteen months. *Galvano-puncture* has been tried five times, but only once with success—in a case under the care of Alcock. Three cases have been successfully treated by Langenbeck, of Berlin, and one by Dutoit, of Bern, by the *subcutaneous injection of ergotin* into the integuments over the tumor. *Manipulation*, as recommended by Ferguson, has been tried five times: Holmes, once in the hands of Little successfully, once by Ferguson with partial success, and in the three remaining cases without any advantage. The treatment undoubtedly deserves a

further trial in these cases, when we consider the extreme danger of the disease and the great want of success that attends other means of cure.

Ligature of the brachio-cephalic, and of the subclavian artery, internal to, behind, and beyond the scalenus anticus, has been practised for the cure of this form of aneurism; it has likewise been proposed to apply the distal operation to the treatment of this disease, and to amputate at the shoulder-joint.

When an aneurism is situated on the right subclavian artery on the tracheal side of the scalenus, there is no way in which the flow of blood through it can be arrested, except by the ligature of the brachio-cephalic artery. When it is situated beyond the scalenus, or even behind it, ligature of the vessel has been practised in the first part of its course before it reaches this muscle. For subclavian aneurism on the left side, in these situations, no operation conducted on the Hunterian principle would be practicable.

Let us now proceed to examine the results that have attended these operative procedures.

Ligature of the Brachio-cephalic.—The brachio-cephalic artery, as may be seen by the accompanying table, has been ligatured sixteen times, and in

CASES OF LIGATURE OF BRACHIO-CEPHALIC ARTERY¹

OPERATOR.	SEX.	AGE.	NATURE OF DISEASE.	RESULT.	REMARKS.
1. MOTT	m.	57	Subclavian aneurism.	Died on 26th day	Tied an inch below h. ligation. Ligature separated on fourth day. Hemorrhage on 26th day, stopped by pressure occurred on 26th.
2. GRAFE.	Subclavian aneurism.	Died on 27th day	Ligature separated in fourteen days. Died of hemorrhage.
3. HALL.	Subclavian aneurism.	Died on 5th day	Artery was diseased and gave way. Bleeding arrested by plug. Death from other cause.
4. DUPUY-TREN.	Died.	Case referred to as occurring in the practice of Dupuytren.
5. NORMAN	m.	...	Subclavian aneurism.	Died.	Died of peripneumonia six hours after operation.
6. BLAND	m.	21	Subclavian aneurism.	Died on 18th day	Hemorrhage came on on the 17th and 18th days. Ligature applied to upper portion of artery.
7. LIZARK	Subclavian aneurism.	Died on 21st day.	Ligature separated on 17th day. Hemorrhage on 18th.
8. HUTIN	m.	26	Hemorrhage from axilla after ligature of subclavian	Died in 12 hours	Punctured wound in axilla for which subclavian was tied. Secondary hemorrhage, and then brachiocephalic tied.

¹ These are all the cases of ligature of the brachio-cephalic artery the details of which I have been able to collect. This artery is supposed to have been once ligatured by Pirogoff and twice by Regardet—and three cases fatal—but, as I can find no details of these operations, I have omitted them in the above table. Guist, in his *Report on Surgery* ("Archiv für Klinische Chirurgie," vol. 31, 1862), says, in speaking of Cooper's second case: "This is the first fatal case of ligature of the brachio-cephalic artery, and every one of them has proved fatal." In the Index Catalogue of the Library of the Surgeon-General's Office, Washington, is a reference to a paper by P. L. Rogers, on "A case of successful ligation of the innominate artery," *American Medical Times*, New York, 1864. I cannot find a reference to this case elsewhere, and have not been able to look up the original paper before these sheets went to press.

CASES OF LIGATURE OF BRACHIO-CEPHALIC ARTERY—*Continued.*

OPERATOR.	SEX.	AGE.	NATURE OF DISEASE.	RESULT.	REMARKS.
9 ARNDT.	Subclavian aneurism.	Died on 8th day.	Inflammation of lung, pleura, and aneurismal sac.
10. COOPER. San Francisco.	m.	...	Subclavian and carotid aneurism.	Died on 9th day.	Upper end of sternum and inner end of clavicle removed. Dyspnoea and retention of urine: pus in the right kidney.
11. COOPER. (Do.)	m.	...	Subclavian and carotid aneurism.	Died on 34th day.	Bones removed as in previous case. Patient was apparently doing well, when secondary hemorrhage appeared. Immediate cause of death, hemorrhage, in consequence of removal of bandages by patient.
12. GORE. Bath.)	m.	52	Subclavian and axillary aneurism.	Died on 17th day.	Artery cut through by ligature. Cardiac extremity not contracted, but partially plugged with dark coagulum. Inflammation of subclavian vein (left). Pus in anterior mediastinum. Aneurism contracted and filled with coagulum.
13. SMYTH. New Orleans.	m.	32	Subclavian aneurism.	Recovery.	Ligature applied to brachio-cephalic a quarter of an inch below bifurcation, and at same time to carotid one inch above origin. Hemorrhage on 15th, 33d, and 51st days, arrested by pouring shot into the wound. Ligature of right vertebral on 54th day. Tumor returned ten years afterwards and proved fatal.
14. BICKERSTETH. Liverpool.)	m.	40	Subclavian aneurism.	Died on 6th day.	Direct compression tried on the artery for two days. Then ligatured above and below the spot where compression had been applied. Death from hemorrhage.
15. O'GRADY. Dublin.)	Subclavian aneurism.	Death next day.	Carotid also tied. Apoplectic symptoms.
16. W THOMSON. Dublin.)	m.	49	Subclavian aneurism.	Died on 42d day.	Secondary hemorrhage 30th and 39th days.

N B —The artery was cut down upon, but not actually ligatured, by Porter, Post, Aston Key, and Hoffmann.

every instance but one with a fatal result. In four other instances the operation has been commenced, but abandoned owing to unforeseen difficulties, and this by some of the most skilful operators that their respective countries can boast of.

Although, in reasoning on the propriety of performing an operation, it is not in general worth while to take into consideration the difficulties that a Surgeon may encounter, provided the operation be at last applicable: yet, when we consider the fact of the ligature of the brachio-cephalic having been attempted, and in consequence of unforeseen and insurmountable difficulties left unconcluded in so large a proportion as one-fifth of the cases, and these in the hands of Surgeons who were as well able as any to accomplish what-

ever was in the power of operative surgery to do, we may well hesitate upon the difficulties that meet the operation itself, before proceeding to the consideration of its results. The difficulties to which I allude do not consist merely in the position and anatomical relations of the vessel, but rather in the condition in which the artery and the adjacent structures may be found after the vessel is exposed. Thus, in Porter's case, the aneurism, which was a large one, occupied the whole of the inferior posterior triangle of the neck, being nearly six inches broad, as no pulsation was traceable in the vessels below and the aneurism, it was useless to attempt ligature on the distal side. On exposing the brachio-cephalic, that vessel was found to be diseased, and it was not thought desirable to pass the ligature round it. In consequence of the exposure of the artery, however, the pulsation in the tumor gradually diminished, and at last ceased entirely, its bulk also becoming less.

In Key's case, in which it was impracticable to pass the ligature, it was found after death that the brachio-cephalic was diseased, being dilated immediately after its origin into an oblong tumor, which occupied the whole of the artery. It is remarkable that in this case, as in Porter's inflammation seems to have taken place in the artery in consequence of the necessary handling to which it was subjected, and that the pulsation in the sac consequently diminished.

The difficulties of the operation are in themselves of serious magnitude; arising from the depth of the vessel, from its proximity to the centre of the circulation, and from the neighborhood of large veins, which may become turgid, and a wound of which not only obscures the line of incision with venous blood, but induces a risk of the entrance of air into the circulation. The trunk of the artery lies behind the sterno-clavicular articulation and the upper part of the sternum, and bifurcates at the level of the upper border of the clavicle. In front of it are the sterno-hyoid and sterno-thyroid muscles, and it is crossed near its upper part by the right inferior thyroid vein, and lower down by the left innominate. To the right side is the right innominate vein. The pneumogastric nerve is behind and to the outer side, not being in close relation with the artery. Behind the vessel are, at first the trachea, then the pleura, the trachea being now internal to the artery. The artery may be reached in the dead body by an incision starting from the sterno-clavicular articulation, and carried upwards for about three inches between the two heads of the sterno-mastoid, but this would not be justifiable in the living subject, as it does not give sufficient space. The early steps of the operation should be the same as in ligature of the lower part of the carotid (see Ligature of the Carotid, p. 193). The sterno-hyoid and sterno-thyroid muscles must be freely divided, and the carotid exposed as low down as possible. This vessel serves as the guide to the innominate, the finger being passed along it till the bifurcation of the main trunk can be felt. The needle is then guided by the finger, and passed round the artery from the outer side. It is evident that the vessel cannot be clearly exposed in this mode of operating, and the needle is therefore passed somewhat in the dark. To overcome this difficulty, Cooper removed the inner end of the clavicle and part of the sternum in both his cases, and should the operation be repeated it is probable that this would be the safest plan of exposing the vessel; at any rate the operator should be prepared to adopt it as an extension of the proceeding first described if necessary. Even when the difficulties of exposing the artery have been surmounted, and it has been exposed, its coats may be found so diseased, or its calibre so increased, that it may be undesirable or impossible to pass a ligature round it. The failure in defining the artery would, however, as we shall immediately see, appear to be dangerous in its consequences than success in the attempt; for of the

three cases that have just been referred to, in which this attempt was made and did not succeed, one was cured of the disease, the artery being obliterated by thrombosis, consequent upon inflammation of its coats, set up by the manipulation during the operation; and in another, Key's patient, an attempt to set up this process appears to have been made, the tumor becoming solid and ceasing to pulsate; whereas, in every case but one in which the vessel was ligatured, a fatal result speedily ensued.

The results of the ligature of the vessel are then in the highest degree discouraging, for of the sixteen cases in the table in which it has been done, only one has recovered. The only successful case, that in which Smyth, of New Orleans, was the operator, is one of the most remarkable on record, but in reality affords no evidence as to the possibility of safely ligaturing the brachio-cephalic trunk. For in this case the carotid was also tied so as to stop the regurgitant flow of blood; yet, notwithstanding this precaution, on the fourteenth day severe hemorrhage to syncope occurred. This hemorrhage recurred at intervals for a period of thirty-seven days, and was temporarily arrested by filling the wound with shot, till, on the fifty-first day after the operation, a "terrific" hemorrhage took place, stopped by syncope. As the bleeding came from the distal side and from the subclavian artery, the vertebral was tied, with perfect success—no bleeding recurring. This fact is of the utmost surgical value: it shows that the secondary hemorrhage, which may be looked upon almost as the necessary sequence of the ligature of the innominate artery, may be arrested and the patient's life saved by the ligature of the principal arterial branch that communicates with and that carries regurgitant blood into the distal end of the artery which was originally ligatured. This fact is entirely new in operative surgery; and the establishment of it, as well as the skill and courage that were displayed in the operative procedures required in, and the general management of this case reflect the highest credit on Smyth. I am indebted to him for the further history of this unique case. After ten years of good health, in which the patient was able to follow his employment as a ship's steward, the pulsation returned and the tumor reached a size larger than before. Thinking it might be fed by the internal mammary, Smyth ligatured that vessel, but without any result. About six months after an abscess formed over the sac, and the aneurism became diffused into it, and as a last effort to save the patient's life, Smyth performed the heroic operation of laying open the sac. The hemorrhage was profuse, and the openings of the vessel into the sac could not be seen, so that the operator had to content himself with plugging the wound. The patient died a few days after. The post-mortem examination showed that the circulation had been carried on chiefly by means of the anastomoses between the aortic intercostals and the branches of the axillary artery. In three more cases the operation of ligature of the innominate is said to have been tried with speedily fatal results, and in four cases, after being commenced, it was abandoned. Death occurred from secondary hemorrhage in eight cases, from inflammation of the lungs or pleura in one; from peritonitis in one, from diseased kidney in one; from phlebitis and suppuration in one, from "apoplectic symptoms" in one; and in three from causes that are not mentioned.

In one case, that of Hall, the artery was transfixed by the aneurism-needle; hemorrhage occurred at the time, which was arrested by plugging, and did not recur, the patient dying from other causes. In three cases, those of Mett, Bland, and Lazari, the hemorrhage came on shortly after the separation of the ligature; but in Grate's it did not occur for fifty-one days after the division of the artery having then probably given way under the influence of some imprudent movement on the part of the patient. In

Cooper's second case, the patient appeared to be going on well for some weeks, when secondary hemorrhage appeared. Learning that nothing further could be done, the patient tore off the bandages when alone, and bled to death. In Bickersteth's case, the artery had been injured by the previous compression applied by means of a leaden wire. The ligature was applied on each side of the bruised spot; but secondary hemorrhage proved fatal on the sixth day. With such results as these, there can be but one opinion as to the extreme danger of such an operation. As its performance has hitherto in every instance, except in Smyth's, entailed death, and generally a speedy death, it should without doubt be undertaken with much hesitation; and it could only be as a last resource that a Surgeon would have recourse to such a procedure, in the face of the consequences that have hitherto invariably followed the application of a ligature to the brachio-cephalic artery for subclavian aneurism. Thomson's case is the only one in which a ligature not intended to cut through the coats of the artery has been applied. In his case the material used was the ox-aorta ligature recommended by Barwell. Although the patient died from secondary hemorrhage on the forty-second day, the result was to some degree encouraging, for the blood had escaped from an ulcerated opening at the bifurcation, and not from the seat of ligature. The opening seems to have been the result of ulceration from a small cavity left after partial healing of the wound, and it seems probable that the blood was supplied by a recurrent stream through the vertebral.

Ligature of the Subclavian.—Poland collected twenty-one cases in which this artery has been tied in the third part of its course for subclavian or subclavio-axillary aneurism. Of these nine recovered. The sac was punctured in two cases—by Liston and Travers. The majority of the deaths were from hemorrhage. Warren relates a remarkable case occurring in a lady aged thirty, who was afflicted by an aneurism just above the clavicle. The patient was excessively deformed from club-foot and curvature of the spine, so that the first two ribs rose above the clavicle, passing obliquely across the neck and carrying the artery upwards and backwards, so that it lay parallel to, and about an inch from, the external border of the trapezius. This peculiarity of position enabled Warren to tie the artery on the cardiac side of the tumor, and the case had a successful issue. For aneurisms situated on the right subclavian artery, behind or beyond the scalenus, that vessel has been *Ligated on the Tracheal side* of these muscles: on the left side this operation is scarcely practicable, on account of the depth at which the artery is situated. It has, however, been performed in one case by Dr. J. R. Rodgers, of New York; and it was attempted once by Sir Astley Cooper, who failed to secure the vessel, and is said to have wounded the thoracic duct. In another case McGill exposed the artery, and temporarily compressed it with a pair of forceps. The pleura was wounded in the operation, and the patient died on the sixth day of pleurisy. When we consider the anatomical relations of that portion of the right subclavian which intervenes between the brachio-cephalic artery and the tracheal edge of the scalenus anticus muscle, we are at once struck with the great difficulties of this undertaking; and when we reflect on the position in which the ligature will be placed between the onward current of blood in the brachio-cephalic on the one side, and the regurgitant stream conveyed by the vertebral, the thyroid axis, the internal mammary and superior intercostal, into the subclavian, immediately beyond the seat of deligation on the other side, we can scarcely, in accordance with those principles on which the formation of a conglutulum within a ligatured vessel takes place, anticipate any but the most disastrous results.

In reference to the mere difficulties of the operation, Fergusson justly characterizes it as the most serious in Surgery; the proximity of the common carotid artery on one side, the internal jugular vein on the other, the vena innominata below, the vagus and numerous small venous trunks in front, the recurrent laryngeal nerve and pleura behind, constitute relations of sufficient importance to justify Fergusson's opinion. But supposing these difficulties overcome, and the ligature applied, this must be situated, as has just been stated, in such a position, with a strong current of blood flowing upon each side of it, as to render the formation of an internal coagulum impossible, and thus up to the present time secondary hemorrhage has invariably occurred when the ligature separated. Whether the application of an absorbable ligature without division of the coats of the artery will be more successful remains to be seen. Besides the danger of secondary hemorrhage from these causes, there would be the additional risk of the coats of the artery being diseased, as we commonly find them to be in a more or less morbid state in the immediate vicinity of aneurisms; and, thus being rendered insusceptible of healthy repair, ulceration and sloughing would take place along the track of the ligature, causing the probability of a recurrence of hemorrhage. Thus, in Colles's case it was seen, on exposing the subclavian artery, that the aneurism had extended in such a way towards the carotid, that it was doubtful whether any part of the affected vessel continued sound. On exposing fully, it was found that only a space of the vessel three lines in length remained free between the sac and the bifurcation of the brachio-cephalic, and it was in this narrow space that the ligature was applied.

The subclavian has been ligatured on the tracheal side of the scalenus in fourteen cases, all of which proved fatal: twelve from hemorrhage, one from inflammation of the pericardium and pleura, and one from pyæmia.

The cases are as follows:

SURGEON.	SEX.	AGE.	DATE OF DEATH.	CAUSE OF DEATH.
COLLES.	m.	33	4th day.	Hemorrhage.
MOTT.	f.	21	18th day.	Hemorrhage.

Thus it will be seen that, while the operation is bad in principle, it is most unfortunate in practice. This appalling Table needs no comment. It is, to my mind, conclusive as to the merits of the operation, the patient having, in every case but two, been carried off by secondary hemorrhage from the distal side of the ligature, in consequence of the close proximity of numerous col-

¹ In this case the carotid was also tied, but the hemorrhage came from the subclavian Fig. 477.

lateral branches (Fig. 476); and in the two exceptional cases the operation, although performed skilfully, proved fatal in one instance from pericarditis and pleurisy, and in the other from pyæmia, before the period at which secondary hemorrhage might have been expected. Liston, in one case, ligatured the root of the common carotid, as well as that of the subclavian, hoping in this way to diminish the risk of secondary hemorrhage, by arresting the current of blood which, by sweeping into the carotid past the mouth of the subclavian, would necessarily wash away any coagulum that might be formed in this artery. But his expectations were not realized: hemorrhage took place as usual, and from that portion of the artery which lay on the distal side of the ligature, the blood having been carried into this end of the vessel in a retrograde course, through the connection existing between the vessels arising from it at this point, and those on the opposite side of the head and neck, as illustrated by the annexed cut (Fig. 477), taken from the preparation of the case in the University College Museum. Indeed, this is the great danger to be apprehended after ligature of the subclavian artery on the tracheal side of the scalenus, depending as it does on the anatomical

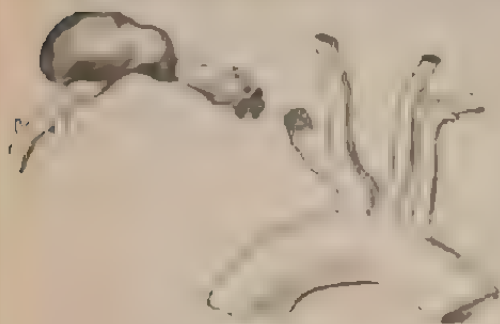

Fig. 476. Ligature of the Subclavian in the First Part of its Course, by Liston.

Fig. 477.—Ligature of the Subclavian and Carotid for Subclavian Aneurism, by Liston.

relations and connections of the vessel, which no skill on the part of the operator can in any way lessen, and which, in my opinion, ought certainly to cause the operation of ligature of the subclavian in the first part of its course to be banished from surgical practice, unless further experience shows that absorption ligatures can be applied with certainty in such a way as to occlude the artery without division of its coats.

The method of operating that has been most commonly adopted is the same as that already described for ligature of the root of the carotid. When the vessels are exposed, the jugular vein is drawn outwards with a copper spatula, and the subclavian is thus brought into view. The needle is passed from below upwards.

When an aneurism is situated on the subclavian artery, in the posterior inferior triangle of the neck, it is necessarily impossible to ligature that vessel beyond the scalenus, as there would not be sufficient room for the exposure of the artery, which, even if laid bare, would in all probability be found in too diseased a condition to bear the application of a ligature.

Thus it will be seen that, in every case, except Smyth's, in which an aneurism of the subclavian artery has been subjected to operation, whether

the ligature of the brachio-cephalic or of the subclavian itself *internal* to the aneurism, the result has been a fatal one. As this unfortunate termination is in no way to be attributed to want of skill on the part of the operators—who have been, without exception, men greatly distinguished for the possession of this very quality—but is dependent solely on certain anatomical peculiarities in the arrangement of these vessels, by which their successful ligature has been rendered all but impossible, a repetition of these attempts, which may hasten the patient's death, can at present scarcely be considered justifiable. What, then, are we to do? Are we to leave patients laboring under aneurism of the subclavian artery to inevitable death, without making an effort to save them? Or does Surgery offer other modes of treatment besides those just mentioned, by which we may hope to arrive at more successful results?

Without mentioning direct pressure, manipulation, or galvano-puncture, which are certainly deserving of further trials in combination with appropriate constitutional treatment, three modes of treatment present themselves:

1. Compression of the Artery where it passes over the First Rib, and consequently on the Distal Side of the Tumor.
2. Ligature of it on the Distal Side, above or below the Clavicle.
3. Amputation at the Shoulder-joint, and Distal Ligature of the Artery.

1. Compression of the Artery on the Distal Side of the Sac could be effected only where it crosses the first rib, and consequently would be applicable only to aneurisms of the first part of this vessel. This plan has never been tried; partly, perhaps, on account of the difficulty in applying pressure in this situation, and partly, probably, on account of the want of success that has attended procedures of this kind when applied to vessels in other situations.

The difficulty in applying the compression might, I think, be overcome by the use of an instrument of which a representation is given by Bourgery. The efficiency of the compression would be materially increased by the employment of direct pressure on the tumor, or of galvano-puncture or amputation at the same time, and in this way a coagulum might be formed in the sac. Although too much ought not to be expected from this mode of treatment, yet, I think, it might with propriety be tried in cases of the kind that have been mentioned.

2. Distal Ligature of the Subclavian Artery in the Third Part of its Course has been suggested, and may, perhaps, hold out some prospect of success in cases of aneurism situated behind or internal to the scalenus. In an aneurismal sac springing from the artery in this situation, the principal current of blood would, in all probability, be that which is destined for the supply of the upper extremity. Some of the branches arising from the artery before it has passed beyond the scalenus anticus would, doubtless, be more or less compressed, and thus obliterated, by the tumor; or they might be obstructed by an extension of the laminated fibrin over their orifices. If, therefore, the supply to the upper extremity could be cut off, there might be a possibility of those changes taking place within the sac which are necessary for the obliteration of its cavity. The principal obstacles to this desirable result would necessarily be the transverse cervical, and supraclavicular arteries, which, being the two vessels that are more particularly destined to carry on the circulation in the upper extremity after the ligature of the subclavian, would necessarily, if not occluded, undergo dilatation, and thus continue to draw too large a current of blood through the sac for stratification of its contents to take place; and, if they were occluded, there would be danger of gangrene of the arm from insufficient vascular supply.

Dupuytren ligatured the axillary artery under the pectoral muscles for a case of subclavian aneurism, two arterial branches being divided in the incisions through the fat and areolar tissue; and the patient died on the ninth day. This operation could not be expected to succeed; for between the ligature and the sac are the large and numerous alar, acromial, and thoracic branches of the axillary artery, which would continue to be fed by a current sent through the tumor, and thus preclude the possibility of its contents being sufficiently stationary for ultimate contraction and cure to result. Laugier performed the distal operation in a supposed case of subclavian aneurism, which afterwards turned out to be one of the brachiocephalic artery. In addition to Dupuytren's case, the operation has been done by Petrequin, Schub, and Canton, in all instances without benefit.

3. The above-mentioned difficulties are met by a plan of procedure originally suggested, I believe, by Fergusson. It is **Amputation of the Arm at the Shoulder-joint**, followed by **Distal Ligature of the Artery**—a desperate undertaking, truly, but for a desperate disease, it must be remembered, and one that under ordinary surgical treatment is almost incurable.

The artery might be ligatured before the amputation. "It is known," says Fergusson, "that amputation at the shoulder-joint is generally a very successful operation; so far as this wound is concerned, then, there might be little to apprehend, but the effect on the tumor is not so easily foretold. Ligature of the axillary artery on the face of the stump might here be reckoned like Brasdor's operation; yet there is a vast difference, for in the latter case the same amount of blood which previously passed towards the upper extremity would still find its way down, and probably part of it would run through the sac; whereas, were the member removed, as the same quantity would no longer be required in this direction, the tumor might possibly be much more under the control of pressure. The value of such a suggestion remains yet to be tested, however, and it would be futile to reason upon it at present. It might be a judicious venture first to tie the axillary under the clavicle; and then, if it were found that the aneurism still increased, amputation might be performed, either immediately before or after the separation of the ligature."

Were a case of aneurism of the subclavian artery internal to the scalenus to present itself to me, the plan that I should adopt would be, first, the employment of pressure on the vessel at the distal side of the tumor, if practicable; should this not succeed, I would, if the disease were situated behind or internal to the scalenus, ligature the artery in the third part of its course; and, did that not succeed in checking the increase of the aneurism, I would perform amputation at the shoulder-joint, as recommended by Fergusson. Should the aneurism occupy the artery after it has passed the scalenus, direct pressure on the sac holds out the best prospect of success. Should that fail, I would not attempt the ligature of the artery below the clavicle; as it is an operation the result of which is most unsatisfactory, and would not prevent a large current through the sac for the supply of the collateral circulation of the arm; but I would at once have recourse to amputation at the shoulder, and then ligature the vessel as near as possible to the sac. It is true that, even in this case, the ligature would be below the branches that are given off under the pectoral muscles; but, as the arm would be removed, they could not undergo any dilatation for the supply of the collateral circulation of the upper extremity.

The first case in which this operation was performed, was by Spence in 1864. The patient lived for four years; and, although the aneurism was not cured, the result afforded good promise of success for the future. For the first ten days after the operation, the pulsation was scarcely to be felt;

and when the patient left the hospital the tumor had diminished to one-third of its former size. The artery was tied in two places—where it was cut, and also just beyond the tumor. Before the patient's death—which probably arose from internal aneurism—the aneurism had increased somewhat towards the chest.

Since this Holden and Heath have performed the operation, but without success. In both cases, however, the aneurism was traumatic in its origin, and had attained a large size before amputation was practised. Hence the chances of consolidation and cure were materially lessened.

Ligature of the Vertebral Artery.—This bold and difficult operation was first performed on the living body by Smyth, of New Orleans, who had recourse to it to check regurgitant hemorrhage after ligature of the innominate for subclavian aneurism (p. 215). I will give the details of the operation in the words of Smyth: "The head of the patient being thrown back and slightly turned to the left, an incision two inches in length was made along the posterior border of the sterno-mastoid muscle, commencing at the point where the external jugular vein crosses this muscle and terminating a little above the clavicle; the edge of the muscle being exposed and drawn to the inner side, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra was readily felt and taken for a guide. Immediately before this and in a vertical line with it lies the artery. A layer of fascia was now divided; some loose cellular tissue with lymphatics and the ascending cervical artery were pulled to the inner side; and a separation was made between the scalenus anticus and longus colli muscles just below their insertion into the tubercle, when the artery and vein became visible; the latter was drawn to the outer side (this is important), and the needle passed around the former from without inwards."

In 1881, W. Alexander, of Liverpool, suggested ligature of the vertebral as a means of curing or relieving epilepsy. He performed the operation in several cases at first with apparent benefit, but subsequent observation showed that the improvement was merely temporary. The operation was repeated in two cases by Watson Cheyne. The method of operating was that above described, and the results so far as the operation was concerned were satisfactory in the great majority of the cases.

ANEURISM OF THE AXILLARY ARTERY.

This artery, though less commonly the seat of aneurism than other large vessels, such as those of the ham, the groin, and the neck, yet is sufficiently frequently diseased. This is due chiefly to its situation, its proximity to the shoulder-joint causing it to be subjected to the very varied, extensive, and often forcible movements, of which that articulation is the seat. Amongst the most frequent causes of axillary aneurism, may be mentioned falls upon the shoulder or upon the outstretched hands, and in many cases the efforts made at reducing old-standing dislocations, instances of which are recorded by Pelletan, Flaubert, Warren, and Gibson, the head of the bone in these cases having probably contracted adhesions to the artery, in consequence of which the vessel was torn during the efforts at reduction. Axillary, like subclavian aneurism, occurs more commonly on the right than on the left side, and is met with in especial frequency amongst men; of 37 cases, only 3 occurred in women. I am acquainted with one case only in which both axillary arteries became aneurismal; it occurred to Furner, of Brighton. In this remarkable case both axillary arteries became affected, an interval of about fifteen months intervening between the formation of the two aneurismal tumors; and the subclavian was ligatured on both sides successfully.

SYMPTOMS.—In axillary aneurism there are three sets of symptoms, attention to which will usually enable the Surgeon to recognize the disease; these are, the existence of a tumor in the axilla, the pain that it occasions, and the affections to which it gives rise in the limb.

The precise situation at which an aneurism of the axillary artery presents externally, will depend upon whether it springs from that portion of the vessel that lies above, beneath, or below the lesser pectoral muscle. If from above, it will appear as a tumor seated immediately below the clavicle and occupying the triangular space between the upper margin of the lesser pectoral and that bone; if it be lower down, it will raise the anterior fold of the axilla, being prevented from extending much out of this space by the dense fascia that stretches across from one side to the other. The tumor, which is at first soft and compressible, has a whizzing bruit, and its pulsations, which are expansile, may be arrested by pressure upon the subclavian artery, where it passes over the first rib. It usually increases with great rapidity, owing to the little resistance opposed by the loose areolar tissue in this situation, and most commonly extends downwards and forwards, causing the hollow of the axilla to disappear. In some rare instances, however, the tumor has been known to take a direction upwards under the lesser pectoral, and into the areolar interval above that muscle, or even underneath the clavicle into the acromial angle between it and the trapezius. It is fortunately rare for an aneurism to take such a course, as it would present serious difficulty in the compression or ligature of the subclavian; and there is more than one instance on record, in which the sac has been punctured in the attempt to pass the needle round this vessel. When the aneurism is seated high up, it not unfrequently happens that the clavicle is pushed upwards by the pressure of the tumor beneath it—a complication of considerable moment in reference to the operation, the difficulties of which are greatly increased by it. The pressure of the tumor upon neighboring parts may give rise to serious consequences, thus it may produce a carious state of the first and second ribs, and the compression of the brachial plexus of nerves will occasion pain and numbness in the upper extremity. The affections of the limb occasioned by the aneurism are diminution or extinction of the radial pulse, oedema, coldness, and loss of muscular power. In some cases the brachial artery beyond the tumor would appear to be obstructed, no pulsation being perceptible in it. Compression of the axillary vein may occasion oedema of the hand and arm, with some diminution in the temperature of the limb; and these symptoms, if the tumor attain a very large size, may amount even to indications of impending gangrene.

DIAGNOSIS.—The diagnosis of axillary aneurism is usually readily made; there being but two diseases with which it can well be confounded, viz. chronic enlargement and suppuration in the glands of the axilla, and pulsating tumor of the bones in this region. From glandular or other abscesses, the diagnosis is generally easy; but I have seen some cases in which, pulsation being communicated to their contents by the subjacent artery, it was somewhat difficult to distinguish the nature of the tumors. Here, however, the history of the case and its speedy progress to pointing will indicate its true nature. From medullary tumor, or osteo-aneurism of the head of the humerus, the diagnosis is not always so easy; and there are at least two instances on record in which the subclavian artery has been ligatured for disease of this kind on the supposition of its being an aneurism. In these instances it has, however, generally been observed that the tumor first made its appearance on the forepart of the shoulder, and not in the usual situation of axillary aneurism; that it was from the first firm, smooth, elastic, but nearly incompressible; and that, although it presented distinct pulsation, there was no

true bellows-sound, but rather a thrilling bruit perceptible in it. The most important diagnostic mark, perhaps, is the fact of these tumors forming a prominence in situations in which aneurisms of the axillary artery would not at first show themselves, as at the upper, outer, or anterior part of the shoulder. In more advanced stages, when the substance of the bone has undergone absorption, and its shell has become thin and expanded by the outward pressure of the tumor, there is often a dry crackling or rustling sound perceived on pressure, which is never met with in cases of aneurism.

THE ATTEST.—I am not acquainted with any instance in which an aneurism of the axillary artery, not arising from wound or injury, has undergone spontaneous cure, or been consolidated by constitutional treatment. Compression or ligature of the subclavian in the third part of its course is the only means of cure.

Axillary aneurisms are favorably situated for the employment of *digital compression*. By this means the subclavian can easily be commanded as it passes over the first rib. And the success of this treatment is likely to be great; first, because, the sac being usually large, a considerable quantity of the contained blood is well out of the current of the circulation, readily stagnates, and may thus easily coagulate; and, secondly, because the current of blood through the sac is proportionately small, and thus, if coagulation once begin, may easily be completely arrested. Digital compression, therefore, in my opinion, should always be had recourse to in the first instance. By this means, aided by rest and constitutional treatment, the progress of the tumor may be stayed, and possibly a consolidation of its contents and cure be effected. This occurred at University College Hospital in a patient seventy-one years of age, in whom an axillary aneurism as large as a shaddock and of an actively progressing character was cured by intermittent digital pressure continued at intervals for between two and three weeks, during which time compression was kept up in all about twenty-three hours, the consolidation commencing on the third day of treatment after seven hours of pressure had been tried. Holmes mentions eight cases in which digital compression has been tried. Three of these, under the care of Cmi-sch and Dutoit, and another Surgeon whose name is not mentioned, were of traumatic origin, and of these two were cured. The remaining five were idiopathic. Three of these, under Cooper Forster, Peatson, and Rizzoli, were cured. Two, under Turet and Vanzetti, failed. In Cooper Forster's case the compression was applied twice under chloroform; on one occasion for three and a quarter hours and on the other for eight hours. In Peatson's case the pressure was applied at intervals for a period of nearly three months. In Rizzoli's case the treatment lasted even longer, the cure not being complete for nearly six months. In this case the artery was so dilated and diseased that ligature was impossible. In Dutoit's case the compression was applied for six hours a day for six days. Lund has also recorded a case cured by digital compression in two periods, the first of ten and the second of seven and half hours.

In another case under the care of S. Jones, compression was combined with the application of Eschmarch's bandage to the arm, but without success.

Compression by instruments on the cardiac side can seldom be made applicable to aneurisms in this situation; inasmuch as the pressure that is brought to bear upon the subclavian must necessarily at the same time induce the greater part of the brachial plexus of nerves to such an extent as to be unendurable by the patient. Yet it is not impracticable, and means might be devised to overcome this difficulty.

Ligature of the artery is, however, still the Surgeon's chief resource in the treatment of these cases. The part of the vessel universally selected for the

application of the ligature is, in accordance with the Hunterian doctrine, that which lies on the first rib beyond the scalenus anticus muscle; this part presenting the advantages of being sufficiently removed from the seat of disease to insure the probability of the coats of the artery being in a sound state, of being by far the most accessible, and, when deligated, of allowing the collateral circulation by which the vitality of the arm is to be maintained to remain uninjured. Notwithstanding these obvious advantages presented by the operation of the subclavian over that of the axillary artery, in other words, by performing Hunter's instead of Anel's operation for the cure of spontaneous axillary aneurism, there would appear to be a tendency in the minds of some Surgeons to advocate the latter instead of the former of these operations, and to substitute for one that offers the advantages that have just been mentioned, a procedure that is not only much more difficult in its performance, and that interferes with the collateral circulation, but that is practised upon a diseased part of the vessel, in dangerous proximity to the sac.

Ligature of the Subclavian in the Third Part of its Course.—In order to apply a ligature to that portion of the subclavian artery which intervenes between the outer edge of the scalenus anticus and the lower border of the first rib, the patient should be placed in the recumbent position, the arm depressed as much as possible, and the head turned somewhat to the opposite side. The situation of the external jugular vein should then be ascertained, if possible, before commencing the incision. It may lie at any point between the posterior border of the sterno-mastoid and the edge of the trapezius, most commonly it is close to the former muscle. Occasionally it is wanting. The operation is commenced by drawing the integuments of the lower part of the neck downwards over the clavicle and making an incision about four inches in length upon the bone, dividing the skin, superficial fascia, platysma, and the supra-clavicular branches of the cervical plexus. When the tension is taken off the part, this incision will be found to traverse the base of the posterior triangle of the neck. The chief object of drawing the skin downwards in this way is to avoid any risk of wounding the external jugular vein, for as this vessel perforates the deep cervical fascia about one finger's breadth above the clavicle, it cannot be drawn downwards with the integuments. In some rare cases the cephalic vein crosses the clavicle and joins the external jugular. It would then necessarily be divided in the first incision. The next step in the operation is to find the external jugular vein. In order to do this the deep cervical fascia must be carefully dissected through close to the clavicle; immediately beneath the fascia a quantity of loose areolar tissue is exposed, in which the lower end of the external jugular will commonly be found. As soon as the deep cervical fascia is divided great caution must be used, the areolar tissue being picked up in small pieces with the forceps and scratched through with the point of the scalpel or torn with a blunt probe or steel director. When the external jugular vein comes into view it must be treated according to its position; if at either end of the wound, it may be drawn aside with a blunt hook; if in the middle, a double ligature must be passed and the vein tied in two places and divided between them. Occasionally the transverse cervical and supra-scapular veins form a plexus with the external jugular immediately above the clavicle, and the difficulty of exposing the artery is then greatly increased. The transverse cervical artery lies normally above the wound, and the supra-scapular is concealed behind the clavicle, but in exceptional cases they may be found in the spaces exposed in the operation. They must then be drawn out of the way with blunt hooks. By combined cutting and scratching through the areolar tissue, the external edge of the scalenus anticus is reached; this is the "directing line" down which the finger is run until the tubercle of the first rib is felt. This is the

guide to the artery, which will be found immediately above and a little behind it, covered, however, and bound down by a dense fascia. Immediately above the artery, and in close contact with it, is the lowest cord of the brachial plexus, that formed by the last cervical and first dorsal nerves; beneath the artery is the first rib, upon which it can be felt rolling under the finger when firm pressure is made. At the same time pulsation will be felt, but this must not be taken as a proof that the structure beneath the finger is the vessel, for the lowest cord of the brachial plexus lies so close to the subclavian artery that it receives a communicated pulsation from it. On firm pressure the nerve still retains its round form, while the artery flattens out, and its surface

Fig. 478.—Ligature of the Subclavian in the Third Part of its Course.

becomes slightly concave. The thick fascia covering the artery having been carefully opened with the edge of the knife, the needle is passed from the nerve, as low down as possible, so as to avoid any risk of injuring the pleura by slipping over the upper border of the first rib. The subclavian vein is so far below the clavicle that there is no possibility of wounding it. In a considerable proportion of cases the posterior scapular artery will be found springing from the artery in this part of its course. In 296 arteries examined by Quain, it arose from the third part as a separate branch in 101, or as nearly as possible one in three cases. If this condition is met with, the ligature must be applied as far as possible to the proximal side of the branch. If necessity obliges the ligature to be applied close to the branch, it is perhaps safer to tie this also, as the anastomosis of the vessels in this region is so abundant that the risk of gangrene from the obliteration of a single branch would be very small.

The operation just described is that commonly adopted. In order that it should be easily carried out, it is in the first place necessary that the shoulder should be depressed as far as possible, so as to bring the clavicle down. This is a matter of much importance; for, if the clavicle be thrust upwards by the pressure of a large aneurism, or if it lie high in consequence of emphysema of the lungs, the Surgeon will have to find the artery at the bottom of a deep wound, instead of on a comparatively plane surface. If, therefore, the clavicle cannot be thoroughly depressed, more room must be provided in the superficial parts of the wound. This is done by making a vertical incision upwards, either along the border of the sterno-mastoid or from the middle of the wound for about two inches. As the artery is in these cases approached rather from above than from the front, the structures met with differ somewhat from those already described. The posterior belly of the omohyoid is always exposed, and forms an important rallying point in the operation, and the transverse cervical artery and vein will most com-

monly come into view. The danger of including the lowest cord in the brachial plexus is greater the more the artery is approached from above. The vertical incision should always be made in fat subjects.

In some cases the clavicle may lie so high that the artery cannot be exposed even with the help of the vertical incision. A case occurred to Sir A. Cooper, in which the attempt to ligature the subclavian artery for a large aneurism of the axilla was forced to be abandoned, in consequence of the clavicle being thrust up to too great a height to enable him to reach the vessel. The extent of the difficulty occasioned by this elevation of the clavicle must necessarily depend in a great measure upon the height at which the subclavian artery happens in any particular case to be situated in the neck. It is not uncommon to find it pulsating so high in the neck, that no amount of elevation of the clavicle by a subjacent axillary aneurism could raise that bone above the level of the vessel. In the majority of cases, however, in seventeen out of twenty-five, as shown by Quain in his work on the *Arteries*, it is either below the level of the bone, or but slightly raised above it, so that, if the clavicle were thrust upwards and forwards, the vessel would be buried in a deep pit behind it. Dupuytren was of opinion that the artery coursed high in persons who were thin, with slender, long necks; whereas, in the thick, short-necked persons, with muscular shoulders, it was deeply seated. I have often verified the truth of this observation, both in dissection and in examining the pulsations of the vessel during life.

In order to obviate the difficulty that has occasionally been experienced in reaching the artery when thus buried behind an elevated clavicle, it has been proposed by Hargrave to saw through the bone. The most serious objection than can be raised against this practice, is the fact of the clavicle being sometimes a part of the wall of the aneurism; but, supposing the Surgeon could satisfy himself that this was not the case, I cannot see any objection to this procedure, provided any very great and insurmountable difficulty presented itself in passing the ligature round the vessel without it.

Accidents during Ligature of the Third Part of the Subclavian.—*Wound of the External Jugular Vein* is a most serious accident, as entrance of air is very likely to take place, and may cause immediate death. This accident is avoided by careful dissection, and if the vein is so situated as to be exposed to the risk of injury, it must be divided between a couple of ligatures.

Profuse venous hemorrhage from wound of some of the numerous veins in the neighborhood has more than once prevented the completion of the operation. Should this accident happen, the wound must be plugged and the operation attempted again at some later period.

Wound of the Sac is a somewhat rare accident. In some cases, as has already been stated, the sac passes upwards below the clavicle into the inferior posterior triangle of the neck; when this is the case, the Surgeon incurs the risk of puncturing it from its close proximity to the artery, as it lies on the first rib. This accident happened to Cusack while ligaturing the subclavian in the third part of its course, for a diffused aneurism of the axillary artery. An alarming gush of blood took place, which was arrested by plugging the wound; but the hemorrhage recurred on the tenth day, and the patient died. In a case related by Travers, in which the sac was punctured by the needle, which was being passed round the artery, the blood, which was arterial, did not flow *per saltum*, but in a continuous stream. "The hemorrhage," Travers says, "was more terrific and uncontrollable than I have ever witnessed," and was not commanded by drawing the ligature tight. It was so great that it was doubtful whether the patient would leave the theatre alive, and was arrested only by plugging the wound with sponge-tents. The patient died of inflammation of the pleura. On examination, the aneurismal sac was found to have a pouch-like enlargement upwards, overlying the artery, where it had been punctured.

Inclusion of the lowest cord of the brachial plexus in the noose of the ligature is a more common accident; indeed, the mistake has more than once been committed of tying these nervous trunks instead of the vessel. Thus, Liston, in the first successful case of ligature of the subclavian in this country, passed the thread round the lower nervous cord; but immediately perceiving his error, turned it to account by drawing aside the included nerve, and thus more readily exposing the artery. Dupuytren, in a case of aneurism of some years' duration, succeeded, after an operation that lasted one hour and forty-eight minutes, and which he describes as the most tedious and difficult he ever attempted, in passing a ligature round the vessel, as he believed. After the death of the patient, which occurred from hemorrhage on the ninth day, the artery was found to have been perforated by the needle, and one-half the vessel and the lower cord of the brachial plexus included in the noose. In a case related by Porter, it is stated that the artery communicated such distinct pulsation to the inferior nervous trunk, that there was no means of ascertaining whether it was the vessel or not, except by passing the needle under it.

Puncture of the pleura in passing the needle is not usually recognized as one of the dangers of ligature of the third part of the artery. It may, however, take place, especially if the needle is passed close to the scalenus

anticus and from above, as must often be the case when the clavicle is much raised.

In connection with the ligature of the subclavian in this situation it is impossible to pass over in silence the fact, that in some instances the artery takes a remarkably high course in the neck, and that in some of these instances instead of passing over the first dorsal rib, it has been supported on a supernumerary cervical rib, the anatomical relations being thus seriously disturbed. And again, if this supernumerary cervical rib be unusually short, the vessel may be found to lie between it and the first dorsal. Another abnormality of great rarity is the passage of the subclavian vein behind the scalenus anticus with the artery. This would add greatly to the difficulty of the operation.

Ligature behind the Scalenus Anticus.—If the sac encroach upon the neck, rising above the clavicle, or the artery be not found in the third part of its course, it may be necessary to ligature it behind the scalenus anticus, dividing the outer half or two-thirds of the muscle. This operation should not be considered as distinct from ligature of the vessel in the third part of its course, but rather as an extension of that proceeding, if it be found, for the reasons just mentioned, unadvisable to tie the artery on the first rib; in this way it has been practised by Dupuytren and Liston. In its first steps, as far as the exposure of the scalenus anticus, it is the same as that for the deligation of the vessel in the third part of its course. When this muscle has been exposed, a director must be pushed under it, upon which it is to be divided to the extent of half or two-thirds its breadth, when it retracts, exposing the vessel. During this part of the operation, some danger may be incurred by the phrenic nerve, and the transversales colli and humeri arteriæ, but if ordinary care be taken, this will not be very great. The phrenic nerve lies altogether to the tracheal side of the incision, if that be not carried beyond one-half the breadth of the muscle; and should it appear to be in the way, it may readily be pushed inwards towards the mesial line, being only loosely invested by areolar tissue. I have, however, seen one instance in which the right subclavian artery was ligatured for a spontaneous cylindrical aneurism of the axilla, and the patient died, on the eighth day, of pneumonia; on examination after death, the edge of the scalenus was found cut, and the phrenic nerve divided. Had the injury to the nerve in this case anything to do with the pneumonia? I do not think it improbable; as division of one phrenic nerve, by paralyzing to a certain extent the diaphragm, and so far interfering with the respiratory movements, must necessarily have a tendency to induce congestion of the lung, which would readily run on to inflammation of that organ. I have likewise heard of one case in which incessant hicough followed this operation, and after death the phrenic nerve was found reddened and inflamed, having probably in some way been interfered with during the exposure of the vessel. The transversales colli and humeri arteriæ may be avoided by keeping the incision in the muscle between and parallel to these vessels.

Another important point in reference to the ligature of the vessel in this part of its course is, that in five cases out of six on the right side and in one-half on the left, the superior intercostal arises from the subclavian artery between the scaleni. When this is the case, there would probably be but a slender chance of the occlusion of the artery by ligature in this situation.

One principal danger in ligaturing the subclavian artery at any point above the first rib, certainly arises from interference with the *fascia* which lies between it and the scaleni muscles, separating it from the pleura, and which is continuous with the areolar tissue of the anterior mediastinum, being,

indeed, the deep portion of the ascending layer of what Sir A. Cooper has described as the "thoracic fascia," and which helps to form the superior boundary of the chest, being continuous in the neck with the deep cervical fascia. After the deeper layers of the cervical fascia have been opened, this fine areolar tissue presents itself; and, if septic inflammation be excited in it, the morbid process will readily extend by continuity of tissue into the thorax by the anterior mediastinum, invading ultimately the pleura and pericardium. Hence, whenever it is practicable, the Surgeon should keep the point of the needle close to that part of the artery which lies upon the first rib, as there is less risk here of opening into the deep areolar tissue of the neck.

Results of Ligature of the Subclavian.—The general results of ligature of the subclavian in the third part of its course for spontaneous aneurism in the axillary are by no means satisfactory. Thus of 48 cases of aneurism of the axillary artery, not dependent upon any external wound, in which the artery was ligatured above the clavicle, I found 23 cures against 25 deaths. This result was so unfavorable, and so different, indeed, from what I anticipated, that I was led to analyze carefully the causes of death. I found them as follows:

Inflammation within the chest, etc.,	10 cases.
Suppuration of the sac,	6 "
Suppurative phlebitis,	1 "
Hemorrhage,	3 "
Gangrene of the hand and arm,	1 "
Gangrene of both arms and legs,	1 "
Not stated,	3 "
	<hr/> 25 "

Thus it will be seen that the two most frequent causes of a fatal result following the operation for axillary aneurism, are not those that are usually met with after the ligature of the larger vessels. It would therefore appear to be owing to some special condition, dependent either upon the application of a ligature to the subclavian artery in the third part of its course, or upon the situation and nature of the disease for which that operation is had recourse to; and the important point to be determined is, whether these conditions are the accidental or the necessary consequences of the application of a ligature in this situation for the cure of aneurism in the axilla.

Inflammation of the Contents of the Thorax proved fatal in 10 out of 25 cases, or 1 in 2.5, and is the most frequent cause of death, though not, I believe, the most frequent untoward complication of this operation. It might at first be supposed that, in this respect, the operations on the subclavian artery resembled other of the greater operations, after which pyæmic pneumonia is so common a sequela; but, on closer examination, it will be found that this is not the case. Inflammation, when attacking the thorax or its contents after ligature of this artery for axillary aneurism, is not confined to the lungs, but very commonly affects the pleura and pericardium as well as, or even in preference to, these organs. It would, therefore, appear probable that it arose from causes that are essentially connected either with this operation or with the aneurism itself. These are referable to three heads.

1. Septic inflammation of the deep areolar tissue at the root of the neck may extend to the anterior mediastinum, the pleura, and pericardium. This would appear to have been the cause of death in a patient in whom Key tied the subclavian, and has been especially adverted to by that excellent Surgeon in his relation of the case.

2. The sac may, by its pressure inwards, encroach upon and give rise to inflammation of that portion of the pleura which corresponds to its posterior aspect. This occurred in a case in which Mayo, of Winchester, operated, and is more liable to happen if suppuration have taken place in the sac; when this occurs, adhesion may take place between it and the pleura, or even the tissue of the adjacent lung; and the contents of the suppurating tumor may be discharged into the pleural cavity or air-tubes, and so coughed up. Of this curious mode of termination there are at least two cases on record: one by Bullen, in which the patient recovered; the other by Gross, in which the patient died from the escape of the contents of the sac into the cavity of the pleura.

3. Division of the phrenic nerve would necessarily, by interfering with the respiratory movements, induce a tendency to congestion and inflammation of the lungs; and, although such an accident must be a very rare one in cases of ligature of the subclavian for axillary aneurism, yet it undoubtedly has occurred, as I have myself witnessed in one case.

Suppuration of the Sac is the most common, though not the most fatal, accident after ligature of the subclavian for spontaneous axillary aneurism. It was the immediate cause of death in six cases, and occurred in two of the patients that died of inflammation of the chest; it took place in six cases also that recovered; in all, fourteen cases out of forty-five, or nearly one in three—a much higher proportion than is generally observed in cases of ligature for aneurism.

What occasions this greater frequency of suppuration of the sac in axillary aneurisms than in those in other situations? The chief cause to which it appears to be attributable is the great laxity of the areolar membrane in the axilla, which allows the tumor to increase so rapidly in size as to excite inflammatory action in the surrounding tissues, which may speedily run into suppuration. So long as the contents of the tumor continue fluid, they will necessarily excite less irritation on surrounding structures; but when once they have become solidified, whether by the gradual deposit of laminated fibrin during the progress of the disease, or, more suddenly in consequence of those changes that take place in the contents of an aneurismal sac after the ligature of the artery leading to it, the indurated mass, acting like any other foreign body, sets up inflammation in the areolar tissue that is in immediate contact with it, and thus disposes it to run into suppuration. The more speedily the solidification takes place, the more disposition will there be to the occurrence of this accident, the neighboring parts being unable to accommodate themselves to the sudden extension and compression they are compelled to undergo. It is probable, also, that the proximity of the wound, and perhaps actual injury done to the aneurismal sac during the operation, are, in many cases, the immediate causes of the inflammation and suppuration. The statistics collected by Koch show a much greater mortality in those cases in which the subclavian artery has been tied for spontaneous aneurisms extending above the upper border of the pectoralis minor, than in those below that point. Of 17 of the former 13 were fatal, of 22 of the latter only 10 died.

The period at which suppuration of the sac may be expected to occur in cases of axillary aneurism, after the ligature of the subclavian, must necessarily in a great measure be dependent on the state of the sac at the time of the operation. If inflammation have been already set up around it, it may happen a few days after the artery has been tied. But if this morbid process have not already commenced the period at which suppuration may most probably be expected is between the first and second month. The period at which suppuration and rupture of the sac take place does not

influence the probable termination of the case to any material extent; as, in the cases that prove fatal, death occurred at various periods between the seventh day and the second month; in Aston Key's case, on the ninth day; in Mayo's, on the twelfth; in Belardini's and Gräfe's, at the end of the first month; in Rigaud's, at the sixth week; in B. Cooper's, in the second month. The recoveries, likewise, took place at all periods after the ligature of the vessel, between a few days, as in Porter's, and six weeks, as in Halton's case.

An axillary aneurism that has suppurated may burst either externally, or into the lungs or pleura, or both. It is most usual for it to burst externally; the tumor enlarges, with much pain and tension; a part of the skin covering it becomes inflamed; fluctuation can be here felt, and, if an incision be not made, the tumor will give way, discharging most usually a quantity of dark-colored pus, mixed up with more or less broken-down and disintegrated coagulum, and, perhaps, sooner or later followed by a stream of arterial blood.

Occasionally, but more rarely, the sac, extending inwards, perforates the cavity of the chest and becomes adherent to the pleura, and may give way into its cavity; or, by pressing upon the lungs, may become incorporated with them. Of this remarkable termination two instances are recorded, in one of which recovery took place.

The first case of the kind is one in which Bullen ligatured the subclavian artery for axillary aneurism. Eighteen days after the operation the tumor began to increase, and to take on the symptoms that are indicative of suppuration. On the twenty-sixth day six or eight ounces of bloody pus were expectorated during a paroxysm of coughing, and the tumor suddenly diminished to one-half its size; it was now punctured, and five ounces of the same kind of matter were let out with great relief. When the patient coughed, air passed into and distended the sac through an aperture between the first and second ribs, near their sternal extremities, through which the contents of the tumor had escaped into the lung. The discharge from the external aperture greatly decreased; the cough lessened; and, finally, three months after the operation, the patient was quite well.

Gross tied the subclavian artery for axillary aneurism on the 18th of February. After the performance of the operation the contents of the tumor solidified, and its volume progressively diminished. On the 15th of March, the patient suffered from fever, and slight tenderness on the apex of the tumor was perceptible. On the 16th he was suddenly seized with intense pain in the chest, which was particularly severe at the base of the right lung, and extended up towards the axilla. Respiration throughout the right lung was bronchial, and there was dulness on percussion over the lower ribs; the aneurismal tumor had suddenly disappeared at the time of the attack. On the 18th, the patient experienced a sensation as if a fluid were passing from the pleural cavity into that of the aneurismal tumor; and, upon auscultating, a splashing sound was heard at every inspiration, the noise resembling that produced by shaking water in a closed vessel. On the 20th, he died. Upon dissection, the aneurism was found to communicate by an aperture, one inch and three-quarters in length and an inch and a half in width, with the pleural cavity; this opening was situated between the first and second ribs, and was obviously the result of ulceration and absorption, caused by the pressure of the tumor. Both ribs were denuded of their periosteum. The right side of the chest contained nearly three quarts of bloody serum, intermixed with laminated clots and flakes of lymph; the former of which had evidently been lodged originally in the aneurismal sac.

Besides these cases, a somewhat similar one has been recorded by Neret, of

Nancy. A patient was admitted into the hospital, suffering from hæmoptoe, and on examination was found to have an aneurism of the left subclavian artery as large as a chestnut. He died shortly after admission; and on examination, the aneurism was found to communicate with a large cavity in the upper part of the lung.

The cause of death in Gross's case was probably the fact of the sac opening and discharging its contents into the pleural cavity. This does not appear to have occurred in Bullen's, in which a communication was established directly with the lung, the contents of the abscess finding exit through the air-tubes. The process here was analogous to what occasionally occurs in hepatic abscess when this opens through the lungs, adhesion having previously taken place between the opposed surfaces of the pleura.

In Furner's case of axillary aneurism, both arteries became affected by the disease, and both subclavians were tied in the third part of their course at an interval of about fifteen months. In this most remarkable and interesting case, the result of which reflects much credit on the skill and decision of the operator, the patient, a stonemason by trade, made an excellent recovery from the first operation. After the second operation he progressed most favorably for twelve weeks, by which time the tumor had diminished so much as to be not more than a third of its original size. Without obvious reason febrile disturbance set in, the tumor enlarged again, and showed signs of suppurating. Furner now made a free incision into it through the pectoral muscle, and let out 18 or 20 ounces of very offensive pus and broken-down coagulum. The patient speedily recovered, the tumor disappearing entirely.

The principal danger, and the most frequent cause of death after the suppuration of the sac, is the supervention of profuse arterial hemorrhage. This may occur either from the distal extremity of the artery opening into the sac, or from one of the large branches which serve to support the collateral circulation round the shoulder, such as the subscapular or posterior circumflex, coming off either immediately above or below the sac, or from the sac itself. When hemorrhage does not take place after suppuration of the sac, it must be from the fortunate circumstance of the occlusion of the main trunk, where it opens into the tumor. It can scarcely be from the occlusion of the principal collateral branches; as there would, in this event, be a difficulty in the preservation of the vitality of the limb. It is easy to understand that, if the sac sprang from the axillary, at a little distance above the orifices of the subscapular and circumflex arteries, all that portion of the main trunk which intervenes between the tumor and these vessels might be occluded, and thus hemorrhage be prevented on suppurating taking place, whilst the collateral circulation would take place uninterruptedly through these vessels. If this portion of the artery have not been occluded by inflammation, the safety of the patient must depend upon the accident of a coagulum or piece of laminated fibrin being fixed or entangled in the mouth of the sac. This may prevent for a time the escape of arterial blood, which, on such a plug being loosened, may break forth with impetuosity, and either at once, or by its recurrence at intervals, carry off the patient.

Another danger may be supersadded in these cases on the suppurating of the sac and the supervention of hemorrhage—namely, the occurrence of inflammation of the pleura, lung, and pericardium, from extension inwards of the morbid process going on in the sac.

Secondary hemorrhage does not frequently occur in cases of ligation of the subclavian artery in the third part of its course, except as a consequence of suppurating of the sac. I myself have seen but two cases in which death occurred from hemorrhage taking place from this artery at the part ligatured. One of these happened to Liston, and the preparation is preserved

in the Museum of the College of Surgeons (No. 1695). In this case it may be seen that the artery was diseased at the point ligatured, and that the bleeding occurred, as usual, from the distal side of the ligature. Barwell, taking Koch's table of 79 cases, and adding to it 11 collected by himself, finds that of 32 deaths occurring in the 90 cases, 10 were from hemorrhage from the site of ligature.

Gangrene of the Hand and Arm is but seldom met with as a sequela of the operation we are considering. This is doubtless owing to the freedom of the anastomosing circulation between the branches of the transversalis colli and suprascapular, and those of the subscapular, circumflex, and acromio-thoracic arteries, as well as between the superior and long thoracic and the branches of the intercostals and internal mammary, by which the vitality of the limb is readily maintained. The principal risk from gangrene would doubtless arise from the subscapular artery being in any way occluded or implicated in the disease, as it is on the anastomoses of this vessel that the limb is mainly dependent for its supply of blood. But, at all events, this danger is small, the only case in which it appears to have given rise to a fatal termination being one in which Collis tied the artery; gangrene of the limb came on after much constitutional disturbance, with rapid, weak pulse, thirsts, sweats, restlessness, and delirium. In Blizard's case, there were sloughing of the sac, and pericarditis, the gangrene being confined to two fingers; and in Brodie's case, it occurred in both the lower as well as in the upper extremities, and must, therefore, have proceeded from some constitutional cause altogether independent of the mere arrest of circulation through the subclavian.

Failure of the operation to cure the disease if the above accidents are avoided is a very rare occurrence. A case of this kind occurred to Berkeley Hill in University College Hospital. The subclavian was successfully tied for a large axillary aneurism; there was some inflammation about the sac after the operation, which gradually subsided. Some months afterwards the tumor began steadily to increase in size without pulsation, and finally the sac was laid open and the vessel tied from within, and the patient made a good recovery.

On reviewing the causes of death, it may be reasonably hoped that the average of success will be materially increased by the use of ligatures which do not divide the coats, and by the prevention of septic and spreading inflammation in the wound by the employment of antiseptic dressings.

Treatment of Inflamed Axillary Aneurism threatening Suppuration.—The case of an axillary aneurism becoming inflamed, and threatening to suppurate before the Surgeon has had an opportunity of ligaturing the subclavian artery, is one that is full of important practical considerations, and that admits of little delay; for if the sac rupture, or be opened, fatal hemorrhage is the inevitable result. It would obviously be impossible, in a case of spontaneous aneurism, with any fair chance of success to lay open the tumor, turn out the coagula, and ligature the vessel above and below the mouth of the sac; the coats of the artery, being not only diseased, but still further softened by inflammation and supervening suppuration, would not be in a condition to hold a ligature. There are two other courses open—viz., ligature of the subclavian, or amputation at the shoulder-joint; and in the selection of one or other of these, the Surgeon must be guided by the progress the disease has made, the condition of the limb as to circulation and temperature, and the solidity or fluidity of the contents of the tumor.

If the tumor be of moderate size and circumscribed, and the arm of a good temperature and not very oedematous, *ligature of the artery* may hold out a reasonable chance of success. It is true that this is but a chance: for the blood will, immediately after the noose is tied, be carried by the supra-

scapular and posterior scapular arteries into the subscapular and circumflex, and by them into the axillary at no great distance from the mouth of the sac; or it may enter directly into the mouth of the latter, if the subscapular or circumflex should chance to take their origin from the dilated portion of the vessel. Hence, the only safeguard against the supervention of hemorrhage as soon as the sac has burst or been opened, or has discharged its contents, will be the occlusion by thrombosis of that portion of the artery which intervenes between these two collateral branches and its mouth, or the accidental entanglement in the latter of a mass of laminated fibrin. Yet in the circumstances as to the condition of tumor and limb that have just been mentioned, it would be but right for the Surgeon to give the patient a chance of preserving his arm.

Should, however, hemorrhage occur on or after the discharge of the contents of the sac, the subclavian having previously been ligatured, what should be done? If the bleeding be moderate, an attempt should be made to arrest it by plugging the wound, and by the application of a compress and bandage. If it recur, or be so profuse as to threaten the life of the patient, what course should the Surgeon then pursue? Two lines of procedure are open to him; either to cut through the pectoral muscles so as to lay the sac open fully, and attempt to include the bleeding orifice between two ligatures, or to amputate at the shoulder-joint.

If a Surgeon were to undertake the first of these alternatives in a case of spontaneous aneurism, of which alone we are now speaking, he would, in all probability, find the part in such a condition as would prevent the possibility of his completing the operation he had commenced. After laying open a large sloughing cavity, extending under the pectoral muscles perhaps as high as the clavicle, and clearing out the broken-down coagum contained in it, in what state would he find the artery? Certainly, the probability would be strongly against its being in such a condition as to bear a ligature, even if it could be included in one. Its coats, in the immediate vicinity of the sac, could not, in accordance with what we know to be almost universally the case in spontaneous aneurisms of large size or old standing, be expected to be in anything like a sound firm state, and would almost certainly give way under pressure of the noose; or the vessel might have undergone fusiform dilatation, as is common in this situation, before giving rise to the circumscribed false aneurism, in which case it would be impossible to surround it by a ligature; or, again, the subscapular or circumflex arteries might arise directly from, and pour their recurrent blood into, the sac or the dilated artery, and, as they would lie in the midst of inflamed and sloughing tissues, no attempt at including them in a ligature could be successfully made. In such circumstances as these, the danger of the patient would be considerably increased by the irritation and inflammation that would be occasioned by laying open and searching for the bleeding vessel in the sac of an inflamed, suppurating, and sloughing aneurism, and much valuable time would be lost in what must be a fruitless operation; at the close of which it would, in all probability, become necessary to have recourse to disarticulation at the shoulder-joint, and thus to remove the whole disease at once. I should, therefore, be disposed to have recourse to *disarticulation at the shoulder-joint* at once, in all cases of profuse recurrent hemorrhage, following sloughing of the sac of an axillary aneurism, which could not be arrested by direct pressure on the bleeding orifice, after the subclavian has been tied.

There is another form of axillary aneurism that requires immediate amputation at the shoulder-joint, whether the subclavian artery have previously

been ligatured or not; it is the case of diffuse aneurism of the armpit, with threatened or actual gangrene of the limb.

Ligature of the Axillary Artery.—Should ligature of the axillary artery at any time be required, the vessel may be secured in one of two situations, in the space that intervenes between the lower margin of the clavicle above the pectoralis minor, or in the axilla as it lies on the tendon of the latissimus dorsi.

To expose the artery above the pectoralis minor, the shoulder must be pushed upwards and allowed to fall backwards as far as possible. An incision is then made, slightly curved with its concavity upwards, commencing immediately above and internal to the tip of the coracoid process, and terminating immediately below the clavicle, and about one inch from the sternoclavicular articulation. The skin and fat are divided in the first incision, and the pectoralis major exposed. The fibres of the muscle are separated in the inner end of the wound, and the finger introduced into the space beneath guiding a probe-pointed bistoury, with which the remainder of the muscle is rapidly divided throughout the whole length of the wound. In doing this, several large branches of the acromio-thoracic artery are divided and must be tied at once. The next rallying point is the upper border of the pectoralis minor. This must be found by tearing through some loose areolar tissue with the forceps and a steel director, so as not to wound the branches of the acromio-thoracic artery and vein. The cephalic vein lies at the outer angle of the wound, and is usually not seen. When the pectoralis minor is found, it must be drawn downwards with a copper spatula. In so doing, the costo-coracoid membrane beneath which the artery lies is brought fully into view. This membrane is seldom sufficiently distinct to be recognized as a definite structure, and it can readily be torn through with a pair of forceps and the steel director. It is perforated by the acromio-thoracic

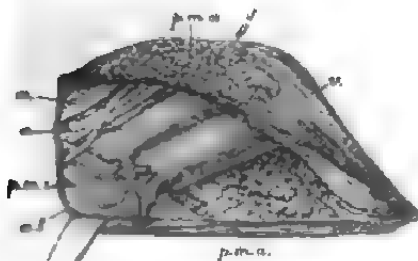

Fig. 481.—Diagram of Ligature of the First Part of the Right Axillary Artery. *p.m.a.* Pectoralis major, the fibres separated in the inner half of the wound and divided in the outer; *p.m.i.* Pectoralis minor; *a.t.* Acromio-thoracic artery and vein; *a.v.* Axillary vein; *a.* Axillary artery; *n.* Brachial plexus.

artery and vein, and the external anterior thoracic nerve. These will be seen as the areolar tissue is torn through, and must be drawn inwards with a blunt hook. In the living body the vein next comes into view, and must be drawn inwards, when the artery will be seen to its outer side. The needle must be passed from the vein and as near the clavicle as possible, well above the origin of the acromio-thoracic. If it is possible to tie only in close proximity to this branch, it would be safer to apply a ligature to it also. In practising the operation on the dead body, the vein often is not seen, and it

is customary to find the artery by following the acromio-thoracic to its origin. There is little risk of including a cord of the brachial plexus, as the nerves lie well to the coracoid side, separated by a slight interval from the artery. It is frequently found in the dead body that the ligature has been applied above the lower border of the first rib, the end of the subclavian being actually the vessel tied. This operation is a very difficult one, on account of the depth of the wound as well as from the embarrassment occasioned by the numerous venous and arterial branches which ramify across the space in which the vessel lies, and ligature of the third part of the subclavian is to be preferred to it whenever it is practicable.

If it is necessary to tie the axillary, as in the case of a punctured wound the operation recommended by Guthrie is probably safer and simpler than that just described. It consists in making an incision from the centre of the clavicle directly downwards, in the course of the vessels, to the middle of the anterior fold of the axilla. In this way the skin, superficial fascia, and greater pectoral muscle, must be successively divided. The lesser pectoral will then be exposed; and the artery may be ligatured above or below this, without further division of muscular substance, or if it be thought desirable to deligate it under this, the muscle must be cautiously cut through. When this is done, a very distinct and firm fascia will come into view; this must be picked up and carefully opened, when the artery and vein will be seen lying parallel to one another, the artery being to the outer side. The vein having been drawn inwards, the aneurism-needle must be carried between it and the artery. The second part of the artery has the three cords of the brachial plexus in close contact with it, the inner lying between it and the vein. At the lower border of the pectoralis minor the inner head of the median crosses the artery. Care must be taken not to include these nerves in the ligature. The great advantage of this operation is, that the wound is open and free, and that, consequently, the artery can be more readily reached in any part of its course. The disadvantage is the great division of muscular substance that it entails. This, however, need not leave any permanent weakness of the limb, as by proper position ready and direct union may be effected between the parts.

The axillary artery may also be ligatured at any point below the lower border of the pectoralis minor, by making an incision parallel to its course in the axilla. The guiding line for the vessel in this situation is obtained by dividing the space between the anterior and posterior folds of the axilla into three equal parts, when the artery will be found to lie at the junction of the anterior with the middle third. The arm being held at an obtuse angle with the trunk, so as to make the skin tense, an incision is made, commencing at the thoracic border of the axilla and extending for a distance of about three inches parallel to the course of the artery. The incision must be made so as to divide the skin only. The fascia, being exposed, must be carefully opened, when the axillary vein will come into view, and must be drawn to one side with a blunt hook. The artery will now be seen surrounded by the nerves of the brachial plexus. In front of it or to its inner side is the internal cutaneous. To its inner side between it and the vein is the ulnar, the nerve of Wrisberg is still further internal, usually beyond the vein. To the outer side is the median, and for a short distance above the external cutaneous lies on the same side of the vessel before entering the coraco-brachialis. Behind is the musculo-spiral, and as far as the upper border of the teres major, the circumflex. The nerves are easily held aside, and the ligature is passed round the artery from the vein. If the ligature be applied near the termination of the axillary artery, as it lies over the tendon of the latissimus dorsi and teres major, it will not be in immediate

contiguity to any large branch. Above this point, it must be applied close to either the subscapular or the circumflex arteries, which would perhaps somewhat add to the danger of secondary hemorrhage. In a fat axilla there is some risk of missing the artery by drifting too much towards the posterior border of the axilla. To avoid this, and also to get rid of the inconvenience caused by the situation of the vein covering the artery, Malgaigne recommends that the incision should be made a little nearer the anterior border of the axilla, and the edge of the coraco-brachialis sought as the first rallying point. When this is found, it is drawn slightly forwards, when the median nerve will be seen in contact with it. If this be drawn on one side, the artery at once comes into view. By this method the artery can often be tied without the vein being seen, and it is impossible to miss the vessels by getting too far to the inner side. Ligature of the axillary is very rarely required for aneurism. It has been done as a distal operation for subclavian aneurism, but without success.

ANEURISM OF THE ARM, FOREARM, AND HAND.

Spontaneous aneurism rarely occurs below the axilla, yet it may occasionally be met with at any part of the upper extremity. Thus Palletta, Pagani, Pelletan, and others, relate cases of spontaneous aneurism at the end of the arm; and Liston states that he once tied the brachial artery in an old ship-carpenter, who, whilst at work, felt as if something had snapped in his arm. Pucher has recorded a case of aneurism under the ball of the right thumb, which was produced by repeated though slight blows with the handle of a hammer used by the patient (a working goldsmith) in his trade; the radial and ulnar arteries were tied immediately above the wrist, and the disease was thus cured. Aneurism has also been met with in this situation after attempted reduction of a dislocation of the thumb. In the Museum of the College of Surgeons there is a preparation of a radial artery with a small aneurism, about the third of an inch in diameter, formed by the dilatation of all the coats of a narrow portion of one-half the circumference of the vessel, a little above the origin of the superficialis volæ. Spontaneous aneurism in the forearm is of extremely rare occurrence. Todd and Arnott (at University College Hospital) have both successfully tied the brachial for spontaneous aneurism of the forearm—in its upper third. DeMorgan records a case of spontaneous aneurism of the ulnar, and Spanton one of the radial artery. In most of the cases in which the brachial artery and its primary branches have been the seat of spontaneous aneurism, disease of the heart and of the arterial system in other parts has coexisted.

While spontaneous aneurisms are rare in these situations, the traumatic forms of the disease are, as has already been stated (vol. i. pp. 458, 462), of more frequent occurrence, and may require ligature of the brachial, or of other of the arteries of the forearm.

TREATMENT.—In cases of aneurism below the axilla, direct pressure may be tried with advantage, provided the tumor be of small size and unattended by inflammation of the superjacent integuments. Compression of the trunk of the artery above the tumor is rarely applicable, on account of the pain that is induced by the pressure upon the neighboring nerves, which cannot be isolated from the artery. Besides this, the brachial artery is so mobile, and the humerus so small and round a bone, that the vessel cannot be steadily compressed against it for any length of time, but will roll away from under the pressure, even if the patient could bear the pain of it. The application of *Kemarch's* bandage under chloroform might be tried in suitable cases.

Ligature of the Brachial Artery.—The brachial artery may be ligatured in the *middle of the arm*, which is considered the seat of election of this operation, by making an incision, about three inches long, parallel to and upon the inner edge of the biceps (Fig. 483), which is the "directing line," and the first rallying point: the fascia, which is exposed, must be opened carefully to a corresponding extent, and the edge of the biceps drawn outwards.

Fig. 483.—Line of Incision for Ligature of the Brachial in the middle of the arm.

when the median nerve will commonly be seen crossing the artery: this must be drawn downwards with a blunt hook, when the artery, accompanied by its two veins, will be exposed; these vessels must then be separated from one another, and the ligature passed and tied in the usual way. In performing this operation, the principal point to attend to is to cut down upon the inner edge of the biceps, which will be the sure guide to the artery. Fig. 484. If the Surgeon keep too low, he may fall upon the ulnar nerve and the basilic vein, which might possibly be mistaken for the brachial artery. by taking care to expose the fibres of the biceps in his early incision, he will avoid this error.

The fascia over the median nerve must be opened thoroughly, otherwise the artery may be drawn on one side with it. The needle must be passed from the nerve.

In the *upper part of the arm* the operation for ligature of the brachial is practically identical with that for the terminal part of the axillary, the inner edge of the coraco-brachialis being taken as the directing line and the first rallying point.

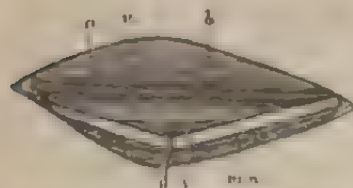

Fig. 484.—Diagram of the parts concerned in Ligature of the Brachial in the middle of the arm. *m. n.*, Median nerve drawn inwards; *b.*, Biceps; *v. v.*, Veins; *a.*, Brachial artery.

At the *bend of the elbow* the brachial artery may be reached by making an incision about two inches in length downwards and outwards, parallel to and immediately above the median basilic vein, when that vessel can be seen; when it cannot, the incision must be at an angle of 45° with the line of the limb commencing about one inch external to and half an inch above the tip of the inner condyle of the humerus, and terminating at the outer side of the tendon

of the biceps. It must not be carried further outwards or the median cephalic vein will be divided. If the median basilic vein is seen, it must be drawn downwards to avoid wounding the ulnar veins which enter it below. As soon as the integumental structures are divided, with the branches of the internal cutaneous nerve, the strong process from the tendon of the biceps to

the fascia of the forearm, the bicipital fascia, comes into view. This must be carefully divided; the artery will be found beneath, having the biceps tendon to its outer side, the median nerve to its inner side, and a vena comites on each side. The needle must be passed from the nerve. It sometimes happens that the operator misses the artery and comes down upon the brachialis anticus which lies beneath it. This muscle is readily recognized by its surface being composed at this part of alternate strips of tendon and muscular fibres. If circumstances require the operation to be performed a little higher up, the edge of the biceps must be taken as the guide, as in the middle of the arm.

Ligature of the Radial and Ulnar Arteries.—These arteries may be ligatured at any part of their course, but the operation is never performed above the middle third of the arm except in cases of direct wound.

The Ulnar Artery above the Wrist may be readily ligatured by making an incision (Fig. 486) about two inches in length along the outer side of the tendon of the flexor carpi ulnaris, which is the directing line to the vessel. The incision should terminate about half an inch above the pisiform bone. If the edge of the tendon cannot be clearly felt, the incision must be made in the line of the artery. This is found by drawing a straight line from the tip of the inner condyle of the humerus to the radial edge of the pisiform bone. The first rallying-point is the edge of the tendon of the flexor ulnaris. As soon as this is clearly exposed it must be drawn inwards with a blunt hook, the wrist being slightly flexed to relax the muscle. A distinct fascia, usually marked by transverse fibres then comes into view; this must be carefully opened and the artery will be found beneath, accompanied by a vein on each side and the ulnar nerve to the ulnar side (Fig. 485). The needle must be passed from the inner side. The artery lies between the tendons of the flexor carpi ulnaris and of the flexor digitorum sublimis and upon those of the flexor profundus. The mistake most likely to be made is carrying the incision too far inwards so as to miss the tendon; the error is recognized by finding fleshy fibres directed downwards and inwards; the tendon is to the radial side of these.

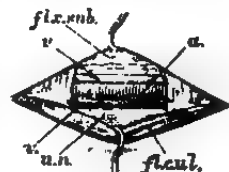

Fig. 485.—Diagram of the Ulnar Artery at the Wrist. *f.d.s.* Flexor digitorum sublimis; *f.c.u.* Flexor carpi ulnaris; *v.* Veins; *a.* Artery.

Ligature of the Ulnar Artery in the Middle of the Arm is a more troublesome operation, as the artery lies deeply on the flexor profundus covered by the superficial muscles of the forearm. It can, however, be reached without difficulty by separating the flexor carpi ulnaris from the contiguous border of the flexor digitorum sublimis.

To find the interval between these two muscles, a line must be drawn from the tip of the inner condyle of the humerus to the radial edge of the pisiform bone. This line corresponds to the outer edge of the flexor carpi ulnaris and also, in its lower two-thirds, to the course of the artery. The upper part of the artery passes beneath the superficial muscles of the forearm from the middle of the hollow in front of the forearm to the junction of the upper and middle thirds of the line just mentioned. The operation is thus performed: the guiding line having been found, an incision two inches in length is made in it (Fig. 486) through the skin and fat. A white line comes into view formed by a few tendinous fibres in the edge of the flexor ulnaris. If more than one white line is seen, a piece of ligature thread may be placed with one end on the inner condyle, and the other on the radial edge of the pisiform bone; the line corresponding to this is the one sought for. The point of the

can lightly along the radial side of the line, after which the flexor carpi radialis and flexor ulnaris can be easily separated with the hand. The direction of the interspace is towards the ulna. On separating the muscles, the artery may appear at once with a vein on each side resting on the flexor profundus. More commonly the ulnar nerve is first seen, when this comes into view, the flexor sublimis must be raised and turned outwards, when the artery will be found coming out from beneath it, and the nerve lower down. The needle must be passed from the inner

Fig. 486.—Lines of Incision for Ligature of the Brachial Artery at the bend of the elbow, and the Radial and Ulnar Arteries in the forearm and at the wrist.

side. The common error in this operation consists in making the incision too much to the radial side and opening the interval between the flexor sublimis and the palmaris longus by mistake. The error is at once recognized by finding that an interspace leads towards the radius instead of the ulna.

The **Radial Artery above the Wrist** may be ligatured by making an incision about one and a half to two inches in length, a quarter of an inch outside the tendon of the flexor carpi radialis—the “directing line:” when after the division of the superficial and deep fasciæ, the artery accompanied by its two veins will be exposed (Fig. 487), and may be tied in the usual way. The artery lies between the tendons of the flexor carpi radialis and supinator longus, and is separated by some fat from the pronator quadratus.

Fig. 487.—Diagram of the Radial Artery. *f. rad.*, Flexor carpi radialis, c.c. Veins, u. Artery.

The **Radial Artery in the middle of the Forearm** can easily be ligatured by an incision (Fig. 486) made in a line drawn from the middle of the hollow in front of the elbow to the root of the styloid process. At this part it is overlapped by the belly of the supinator longus, and lies on the insertion of the pronator teres. The incision should be about two inches in length; after the fasciæ is divided the supinator comes into view, its internal edge must be found and the muscle turned outwards. A dis-

tinct fasciæ is found beneath it, on opening which the artery will be seen with a vein on each side. The radial nerve is about half an inch to the outer side, and is usually not seen.

Ligature of the Radial Artery at the Wrist has sometimes been done for aneurism of the palm, but is more commonly required for wound. The artery at this part of its course lies deeply on the external lateral ligament of the wrist-joint. It winds round the lower end of the radius, passing beneath the extensor ossis metacarpi and extensor primi internodii pollicis, and then under the extensor secundi internodii. The operation is performed by making an incision from the base of the metacarpal bone of the thumb

to the posterior part of the root of the styloid process of the radius in such a way as to be midway between the tendons of the extensors of the first and second phalanges of the thumb. In the superficial fat will be found the radial vein (which must not be mistaken for the artery) and some branches of the radial nerve. A fascia extending between the two tendons is then found and carefully opened, when the artery will be seen crossing the wound obliquely rather towards its lower end. This operation should never be performed in preference to that in front of the wrist, as it is more difficult, and is apt to leave some stiffness in the tendons of the extensors of the thumb.

CHAPTER XLV.

ANEURISMS OF THE ABDOMEN AND LOWER EXTREMITIES.

ANEURISM OF THE ABDOMINAL AORTA AND ITS BRANCHES.

As, until recently, any surgical treatment of these aneurisms was considered impossible, they were left entirely in the hands of the physician; but since the introduction of compression of the aorta under prolonged anaesthesia, by Murray, of Newcastle, they have become fairly entitled to a place in a work on Surgery.

Aneurism may affect the abdominal aorta at any part of its course, but the most common situation is near the origin of the coeliac axis; and here the disease is often not confined to the main trunk, but one or more of the branches are also affected. The situation next in order of frequency is at or near the bifurcation. Aneurisms may form in connection also with any of the main branches of the abdominal aorta, most frequently on the superior mesenteric, splenic, and inferior mesenteric. The aneurism may be sacculated or tubular. When growing from the main trunk, it is usually of the former variety.

SYMPTOMS.—The chief sign of the disease is the existence of a pulsating tumor, situated in or near the middle line, somewhere between the costal margin and the region of the umbilicus. The pulsation of the tumor is of the expansile kind characteristic of aneurism, and there is frequently a distinct bruit. Walshe mentions a single systolic murmur, a dull muffled systolic sound convertible into a murmur by a little pressure, a sharp, abrupt, short systolic murmur on the left side of the lumbar spine, a systolic murmur audible below the sac, but not over it, and occasionally a dull second sound, as having been heard in various cases of abdominal aneurism. The exact shape and size of the tumor and the nature of its pulsation can in many cases be ascertained only by fully relaxing the abdominal muscles by the use of chloroform. The sensation of pulsation in the epigastrium may be very perceptible to the patient, or may be entirely absent. Constant aching lumbar pain is a very frequent symptom. The pressure-signs are not usually very marked till late in the disease. Pressure on the vena cava to such an extent as to cause oedema of the lower extremities is almost unknown. The sac may press on the lumbar plexus, and give rise to signs of irritation in the course of its branches. The most marked of these are pains in the groin and testicles from irritation of the genito-crural, and occasion-

ally shooting pains down the thigh, in the course of the anterior crural or external cutaneous nerve. When the bodies of the vertebrae are eroded, constant lumbar pain will be frequently present, of the same burning, boring character as that felt in thoracic aneurism under similar circumstances. In some cases the pressure may affect the great intestine, causing considerable difficulty in defecation. Occasionally the tumor may attain to an enormous size before death, half filling the cavity of the abdomen. The fatal termination may be due to gradual exhaustion from pain and interference with the functions of the abdominal viscera, to sudden rupture of the sac into the peritoneum or subperitoneal tissue, or into some part of the alimentary canal, or, more rarely, into the pleural cavity through the diaphragm.

The **DIAGNOSIS** rests chiefly on the situation of the tumor, its distinct expansile pulsation, the existence of an aneurismal bruit, and the pressure-signs. Very marked *epigastric pulsation* is not an unfrequent symptom in anemic patients suffering from atonic dyspepsia, and in these cases very slight pressure on the artery from a stethoscope will give rise to a distinct bruit. Under these circumstances, it is sometimes not easy to speak positively as to the condition of the artery, but in the majority of cases a careful examination under the influence of chloroform will readily determine the nature of the disease. A *displaced or enlarged heart* also gives rise to distinct epigastric pulsation, but this can hardly be mistaken for aneurism. A *solid mass of feces* accumulated in the transverse colon may receive a very distinct impulse from the aorta, but the doughy feel of the mass, its superficial nature, and the history of the case, will usually readily determine its nature. A *prominent lumbar vertebra* also pushing the aorta forward may simulate a dilatation of the artery. *Cancerous lumbar glands* surrounding the artery may give rise to considerable difficulty in diagnosis; and here again a careful examination under chloroform is the most likely means of arriving at a correct conclusion. *Cancerous tumors* growing from the bones may give rise to almost insuperable difficulties in the diagnosis. From *tumors of the various abdominal viscera*, the diagnosis must be made on general principles. The amount of fat in the abdominal walls necessarily has a great influence on the difficulty or ease of coming to a definite conclusion.

TREATMENT.—In all cases of aneurism of the abdominal aorta, constitutional treatment should be given a fair trial before any more severe measures are adopted. Tufnell has recorded two cases in which a cure was effected by diet and rest—in one case in 21 days, and in the other 37. If this treatment fail, the only resource left is **compression of the abdominal aorta**. The pain of this application is usually very severe, so that, in order to relieve it, patients should be kept under the influence of chloroform for many hours. The credit of introducing this mode of treatment is undoubtedly due to Murray, of Newcastle-on-Tyne. The operation has now been performed for aortic aneurism in nine cases. In six, under Murray, Durham and Moxon, Durham, Greenhow and Hulke, Pollock, and Sir James Paget, the pressure was applied on the proximal side of the sac. Of these, three—Murray's, Durham and Moxon's, and Greenhow and Hulke's—were successful; one, Pollock's, failed; and two, Durham's second case, and Sir James Paget's, were fatal. In three the pressure was applied on the distal side of the sac; one, under Bryant, terminated fatally, and the other two, under Marshall and Barwell, failed. In every case the pressure had been applied by the instrument known in this country as Lister's aortic tourniquet. That this instrument may in some cases be safely applied to the abdominal aorta from the highest point at which the artery can be reached to its bifurcation, is clearly proved by results of the cases above mentioned. In Durham and Moxon's case, it is stated that "by positioning the body of the patient, just

sufficient space was afforded for the introduction of the pad of the tourniquet between the cartilages of the ribs and the aneurism." In Greenhow and Hulke's case, it was applied midway between the xiphoid cartilage and the umbilicus, immediately above the tumor. That three out of the eight cases have terminated fatally shows, however, that the operation is by no means devoid of danger. In Pollock's unsuccessful case the patient suffered from hæmaturia, and in Greenhow's case albumen appeared in the urine after the last operation, thus showing serious interference with the circulation in the kidney. In Marshall's case the patient suffered from retention of urine for some days after one operation, probably from some injury to the hypogastric plexus. In Bryant's case the *post-mortem* examination showed bruising of the mesentery and intestine and peritonitis, and "the tissues about the compressed aorta were loaded with effused blood." In Paget's case an abscess had formed in the mesentery, peritonitis had been set up, and the mesenteric artery was found to be compressed and flattened, and embolic clots were found in its branches. In Durham's fatal case there were signs of bruising about the pancreas, and the aneurism was found to affect the mesenteric artery. The time during which the pressure has been maintained has varied considerably. Murray's case was cured by one application lasting five hours; Durham and Moxon's in 10½ hours; Greenhow and Hulke's, by three applications lasting 35 minutes, 4 hours, and 3 hours. In Marshall's case distal pressure was applied without serious consequences, on one occasion for 18 hours, and on another for 19 hours. Vomiting has been found to be a troublesome complication in several cases. Of the successful cases, Murray's is the only one in which the pulsation of the tumor ceased permanently immediately after the operation. In Greenhow and Hulke's case it did not finally disappear till some days after the last application of the tourniquet; and in Durham and Moxon's, although it ceased at the time, it returned in a few hours, and persisted for a month before it finally disappeared. From the above cases, it will be seen that there is abundant evidence of the safety of the *proximal* operation, and sufficient probability of success to justify us in adopting it in every favorable case. Further evidence is required before abandoning *distal* pressure as absolutely useless. In Bryant's fatal case the sac was found to be filled with firm clot, which was considered to have been sufficient, had the patient lived, to have cured the aneurism. In Marshall's case the tumor was thought to be slightly more solid after the operations, but no permanent effect was produced. The *distal* operation, however, does not seem a very hopeful one. The number and size of the branches coming off from the aorta at its upper part, and the frequency with which the coeliac axis and its large branches are implicated, are very unfavorable circumstances for *distal* pressure. The anastomosis of the collateral vessels is, moreover, so small compared to the immense interference with the direct circulation, that the only effect of *distal* pressure must be for many hours greatly to increase the tension in the vessels above.

In performing the operation of compression of the aorta under prolonged anesthesia, a few points require special attention. The patient should be fed on the day before the operation. On the day of the operation he should receive fluid nourishment only, and the bowels should be well emptied by means of a copious enema. The tourniquet must be applied with the greatest care immediately above the tumor, and with no more force than is absolutely necessary. If much force be required before the pulsation in the *inferior* arteries is arrested, it is probable that the pad of the tourniquet is not in the right place, and various attempts must be made till the spot is found where the smallest amount of pressure will control the circulation. It can be found convenient to insert a soft hollow sponge under the pad of

the tourniquet, as it then accommodates itself more readily to the parts between it and the spine. During the operation the patient must be watched very carefully, and the tourniquet slackened at once if any symptoms of faintness intervene. Obstinate vomiting may render the continuance of the operation impossible. It is difficult to say whether this is due to pressure on the sympathetic or to the influence of the chloroform. During the application of the tourniquet, it is advisable to have the lower limbs raised in the bed and warmly wrapped in cotton wool, as marked coldness and *seriens* *concord* so have usually been noticed after the compression has lasted a short time. If necessary, nutritive enemata and brandy may be administered during the anesthesia.

INGUINAL ANEURISM.

An **Iliac or Inguinal Aneurism** may arise from the external iliac, or from the common femoral artery; most frequently it springs from the latter, and, taking a direction upwards, pushes the peritoneum before it, and thus encroaches somewhat upon the cavity of the abdomen. The aneurism is commonly of the circumscribed false variety, though sometimes tubular. It rarely, if ever, becomes diffused, for the reason long ago pointed out by Scarpa, that the femoral artery, above the edge of the sartorius muscle, is invested by so dense a sheath, and is so closely bound down to the neighbouring fascia, that, when dilated into an aneurism, it does not readily give way.

SYMPTOMS.—When first noticed, the aneurism is a small, soft, compressible tumor, with pulsation and bruit, and is generally attended by little pain or *uneasiness*. It rapidly enlarges, however, and may attain a considerable magnitude; being often somewhat lobulated upon the surface, owing to the unequal constriction exercised on it by the fascia under which it lies. At the same time, it usually becomes more solid; and the pulsation in it diminishes considerably, or even ceases entirely. As it increases in size, it compresses the saphena and femoral veins, thus giving rise to edema of the limb; and, by stretching the genito-crural and some of the branches of the anterior crural nerve, it occasions considerable pain in the thigh and leg.

DIAGNOSIS.—The diagnosis of inguinal aneurism is not always so easy as might at first appear. It has most frequently been confounded with abscess in the groin, with carcinomatous tumors in this situation, and with osteo-aneurism. The diagnosis from *abscess* must be made on general principles; but in some instances it appears to be replete with difficulty, as there are not a few cases on record in which aneurisms in this situation have been mistaken and punctured for abscesses, an error that has three times fallen under my own observation, and one which has in every instance proved fatal. The diagnosis of an inguinal aneurism, solidified by the deposition of laminated fibrin, and pulsating but indistinctly, from a *pulsating sarcoma* in the groin, is surrounded by the greatest difficulty, and cannot, I believe, with the means we at present possess, be accomplished with absolute certainty. The fact of the two diseases having in two instances been confounded by two of the most distinguished Surgeons of the day, Stanley and Syme, is sufficient evidence of the difficulty attending their diagnosis.

TREATMENT.—It occasionally happens that inguinal aneurisms, even of a very large size, undergo spontaneous cure, or become consolidated by direct pressure conjoined with constitutional treatment; but these instances are of such rare occurrence, that such a result cannot be relied on in any one case. Compression of the aorta under prolonged anesthesia has of late years been found so successful, that in no case should a trial of it be omitted when

possible (see p. 242). Should it fail, it becomes necessary to tie the vessel leading to the sac. In the majority of instances the tumor, though it may have encroached on the abdomen, will not have reached too high for the external iliac to be ligatured; should it have done so, however, the Surgeon may have to tie the common iliac artery; but in some instances even this may not be practicable, and his choice must lie between the slender chance offered by constitutional treatment, and the fearful alternative of ligaturing the aorta.

Ligature of the External Iliac Artery.—There are two modes of tying the external iliac artery—the one originally practised by Abernethy, considerably modified by Liston; and the other introduced by Sir A. Cooper.

Abernethy's modified method (Fig. 488) on the right side consists in commencing an incision at a point about one inch above and the same distance

Fig. 488.—Ligature of the External Iliac by Abernethy's Operation, modified.

internal to the anterior superior spinous process of the ilium, carrying it in a curved direction, with the convexity outwards, to a point about three-quarters of an inch above and half an inch external to the middle of Poupart's ligament. When the operation is on the left side the incision should be commenced below and carried upwards between the two points mentioned. The wound thus made is altogether external to the inguinal canal and to the line of the epigastric, and above and internal to the main trunk of the circumflex iliac artery. It is about four inches in length, and, if necessary, in fat subjects may be extended at the upper end. After cutting through the skin and superficial fascia, the tendon of the external oblique is carefully divided, as much as possible in the line of its fibres. The internal oblique and trans-

versalis are next divided with great caution, when the transversalis fascia is reached, and recognized by its dull white appearance. Beneath this membrane there is often a little fat, especially at the lower part of the wound. A small portion of the fascia, at the lower end of the wound, is now carefully raised with the forceps, and cut through with the blade of the scalpel laid on the flat. A broad hernia-director is then introduced, and passed underneath it, when it should be laid open to the full extent of the wound. In doing this care must be taken not to wound the peritoneum. This is most likely to happen in consequence of a fold of that membrane overlapping the end of the director, so that the knife wounds it when run along the groove. To avoid this it is safer not to push the knife quite to the end of the director. The risk of wounding the peritoneum may be also avoided by tearing the transversalis fascia with the fingers instead of using the knife. Both the fascia transversalis and fascia iliaca are firmly attached to Poupart's ligament, so that there is no risk of stripping up the latter fascia in such a way as to displace the vessels. If a hole be made in the fascia transversalis large enough to admit the tips of the two forefingers, it will be found always to tear with the greatest ease to the full extent of the wound. When this is accomplished the whole inner side of the wound is drawn inwards and slightly downwards, the peritoneum being gently separated from its loose areolar connections in the iliac fossa by the Surgeon's fingers; it must be kept out of the way by an assistant, who holds it up with a broad bent copper spatula. The artery will now be felt pulsating at the brim of the pelvis, and is readily brought into view at the bottom of the wound. It is enclosed in a very loose areolar sheath, and has the vein lying to its inner side and the genital branch of the genito-crural upon it. It is crossed near Poupart's ligament by the circumflex iliac vein. The investing areolar tissue must be scratched through, and the needle passed from the inner side between the vessels. When the vessel is much diseased, it is often very tortuous, and may dip down into the pelvis so as to make it difficult to expose it except close to its lower end. Occasionally enlarged glands round the artery give some trouble by obscuring it and rendering it difficult to clean.

In *Sir Astley Cooper's operation* the outer two-thirds of the inguinal canal are opened. An incision is made about three inches in length, beginning close to Poupart's ligament, about half an inch outside the external abdominal ring, and terminating about one inch internal to the anterior superior spinous process of the ilium. The line of incision is not quite parallel to Poupart's ligament, but rather to the fibres of the tendon of the external oblique. In dividing the superficial fascia, the superficial epigastric artery is cut and must be ligatured. The external oblique having been exposed, a small hole is made through the tendon at the lower end of the wound, and a director inserted, on which it is divided to the full extent of the wound, taking care to cut exactly parallel to the fibres so as to injure the tendon as little as possible. The knife may now be laid aside, the subsequent steps of the operation being carried out with a steel director and the forceps. The divided tendon of the external oblique being held open with blunt hooks, the cord, surrounded by the cremaster, and the lower edge of the internal oblique come into view. Some loose areolar tissue and a few fibres of the cremaster must now be scratched through, close to Poupart's ligament, and the finger passed beneath the cord, which must be pushed upwards. The transversalis fascia is then carefully torn through with the director and forceps, and the artery can then be felt covered by a little fat and areolar tissue. Two copper spatulae are then inserted through the opening in the transversalis fascia; the internal of these is drawn upwards and inwards, raising the cord and drawing the epigastric artery out of the way; the external pulls the lower border of the internal

oblique and of the transversalis upwards and outwards. Both spatulae raise the peritoneum. By clearing away a little loose areolar tissue, the artery can be exposed for one inch and a half or two inches without difficulty. It has the genital branch of the genito-crural lying on it, and it is crossed by the circumflex iliac vein a little above Poupart's ligament; the external iliac vein is to its inner side; these must be carefully avoided. The needle must be passed from the inner side not less than one inch above Poupart's ligament, so as to avoid the epigastric and circumflex iliac arteries. After the operation a drainage-tube may be inserted at the lower angle of the wound, and a catgut suture inserted in the divided tendon of the external oblique.

On comparing the two operations, it would appear that the principal disadvantage of Abernethy's is, that it is apt to leave a tendency to hernial protrusion, in consequence of the abdominal wall being much weakened by the free incisions that are necessary through the muscular planes; the great advantage attending it is, that the external iliac may be ligatured at any part of its course, and that, if requisite, the incision may be extended upwards, and the common trunk secured. In Sir A. Cooper's operation, the line of incision lies directly across the course of the epigastric artery, which, as well as the circumflex ilii, if it arise high, and the circumflex vein, which crosses the iliac artery at this point, and is often somewhat funnel-shaped, may be in danger of being wounded. The spermatic cord is likewise somewhat in the way in this operation. Dupuytren actually wounded the epigastric artery in one case; and Houston had much difficulty from the circumflex vein in another instance. This operation has also the disadvantage, that the incision upwards cannot be conveniently prolonged so as to deligate any portion of the vessel except that which lies immediately above the crural arch; but the peritoneum is less disturbed than in the other case, and there is less tendency to hernial protrusion afterwards. As a general rule, I think we may conclude that in cases of spontaneous aneurism, in which it might, from the size of the tumor or the diseased state of the vessels, be found necessary to apply the ligature to a higher point than was intended before the operation commenced, it will be safer to have recourse to Abernethy's plan, modified as above described, for in this way we shall be able to ligature the vessel at any part of its course; whilst in cases of hemorrhage after amputation, or of traumatic femoral aneurism, in which the artery is not likely to be diseased, recourse should be had to Cooper's operation, more particularly if the patient be thin, and the abdomen flat.

In connection with the ligature of the external iliac artery, there are some practical points that deserve mention. Before the operation, the colon should be emptied by means of an enema, and the pubes shaved. The incision in the abdominal wall must be sufficiently extensive.

In Abernethy's method, modified as above described, there is no fear of wounding the epigastric unless the incision be carried too far at its lower end. The artery may be roughly said to run in a line drawn from a point at which the femoral artery crosses the brim of the pelvis to the umbilicus. In either method of operating should the incision implicate the external ring, but it give rise to a tendency to hernial protrusion. Care should be taken not to wound the peritoneum; for, although two patients in whom this was done by Peet and Tait both recovered, yet it is of course a dangerous accident, and should, if possible, be avoided. The peritoneum must not be torn up more than is absolutely necessary, lest hemorrhage or subsequent peritonitis occur. In raising the peritoneum, care must be taken not to displace the artery which lies loosely in the subperitoneal tissue, and can be easily raised in the spatula, or pushed over the brim of the pelvis. The separation of the peritoneum is much facilitated by the Surgeon holding the

1. The first step in the process is to identify the problem or issue that needs to be addressed. This involves gathering information and understanding the context of the problem.

2. Once the problem is identified, the next step is to define the objectives and goals of the project. This helps to clarify what needs to be achieved and provides a clear direction for the team.

3. The third step is to develop a plan or strategy to address the problem. This involves breaking down the problem into smaller, manageable tasks and determining the resources needed to complete each task.

4. The fourth step is to implement the plan. This involves putting the strategy into action and monitoring progress to ensure that the project is on track.

5. The final step is to evaluate the results of the project. This involves assessing the outcomes against the objectives and goals and identifying any areas for improvement.

1. The first step is to identify the problem or question that needs to be addressed. This involves understanding the context and the specific requirements of the task.

Kobe's statistics with Barwell's supplementary cases give somewhat different results. Hemorrhage occurred in 24 of the 141 cases; of these, 9 recovered and 15 died. Gangrene was fatal in 6, peritonitis in 2, retro-peritoneal suppuration in 2, and various other causes in the remaining 6, making a total of 31 deaths in the 141 cases.

The ligature of the external iliac for *aneurismal varix in the groin* affords a striking contrast with that for spontaneous aneurism; the four cases recorded all proving fatal, two dying of gangrene and two of hemorrhage. In these cases Guthrie has recommended that the tumor should be laid open, and the artery ligatured above and below the aperture in it. During the operation the artery may be readily commanded above the seat of disease by the application of the abdominal tourniquet, either to the aorta or to the common iliac at the brim of the pelvis.

Aneurism occasionally takes place *in the groin and ham on the same side*; here the ligature of the external iliac will cure both diseases. Of four cases in which this complication occurred, the operation was successful in three, one patient dying of gangrene; and in him the popliteal aneurism was on the point of bursting at the time of the operation. In two of the three cases that recovered, pulsation returned in the inguinal aneurism, but disappeared after a time.

Ligature of the Common Iliac.—This artery was first tied by Gibson, in a case of gunshot injury, the patient dying of peritonitis and secondary hemorrhage on the thirteenth day. The great American Surgeon, Matt, was the first who tied it for aneurism, the patient making a good recovery. If the aneurism in the groin extend so high that there is not sufficient space for the exposure and ~~ligature~~ of the external iliac artery, it becomes necessary to tie the common trunk. This may be done by extending the incision that serves for the ligature of the external iliac upwards and slightly towards towards the umbilicus, to an extent corresponding to the degree of obesity of the patient, so that it assumes a somewhat semilunar form. If the operation is commenced with the intention of putting a ligature to the main trunk, it is of great importance in determining the length of the incision, and calculating the point at which the artery will be met with, to remember the *different bearings of the parts in the neighborhood of the vessels*, and the *relative frequency with which the origin and termination of the artery correspond with certain fixed points that may readily be detected*.

The points of importance are the relations of the vessels to the lumbar vertebrae, to the crest of the ilium, and to the umbilicus. The ordinary place of division of the abdominal aorta is on the body of the fourth lumbar vertebra or on the intervertebral disk below it; according to Quain, this was the case in three fourths of the bodies he examined, or in 156 out of 196. In regard to the relations between the situation of the bifurcation of the aorta and the crest of the ilium, we find it, according to the same anatomist, to

Fig. 486 - Obliteration of Femoral Vein by Inguinal Aneurism

have ranged in about four-fifths of the cases between half an inch above and below the level of the highest point of this part of the bone. With reference to the umbilicus, no definite rule can be laid down; but it may be briefly stated that the bifurcation of the aorta is a little to its left. As a general rule, that given by Hargrave is perhaps sufficiently good for ordinary purposes. If a point be taken about half or three quarters of an inch below and a little to the left of the umbilicus, and a line be drawn on each side from this point to the centre of Poupart's ligament, we obtain about the direction of the common and external iliac arteries. On dividing these lines into three equal parts, the upper third will correspond to the common trunk, and the lower two-thirds to the external iliac, and the junction of the upper with the middle third to the bifurcation of the common iliac artery.

The point of division of the common iliac artery is, in the majority of cases, opposite the lumbo-sacral articulation; and if it be not in this situation the division will probably be lower down. The length of the vessel varies greatly; according to Quain, in five-sevenths of the cases it ranged between one and a half and three inches.

The artery lies at the brim of the pelvis. The veins on the two sides differ in their relation to the arteries. The left vein lies to the inner side of the left artery, and then passes beneath the right common iliac artery to join the right vein in forming the vena cava inferior. On the right side the vein is at first beneath and then to the outer side. The common iliac artery is crossed by the ureter near its lower end.

The incision to expose the common iliac extends from a point about one inch external to and one inch above the middle of Poupart's ligament in a curved direction to another point about two inches above and the same distance internal to the anterior superior iliac spine. The curve must be such that if prolonged the incision would reach a point about midway between the xiphoid cartilage and the umbilicus. Care must be taken that the incision be not carried too low down or too far forwards; nothing can be gained by doing so, and there is besides the additional risk of the circumflex iliac or epigastric being wounded, as happened to Mott; and as these are the principal agents in the anastomosing circulation, their injury is a serious accident. The muscles are carefully divided, as in the operation for the external iliac, and the transversalis fascia opened in the same way. The peritoneum now comes bulging into the wound, pressed forward by its contents. It must be gently stripped from the iliac fossa by the Surgeon carefully insinuating his hand beneath it, care being taken to raise it directly inwards towards the brim of the pelvis, at which point the external iliac will be found, which serves as a guide to the parent trunk. The ureter always comes up with the peritoneum, and is usually not seen. The peritoneum must be well drawn inwards by broad copper spatulae. The ligature must be passed round the artery on the left side from within outwards, a slight scratch having been made through the fascia, covering the vessel by means of the finger-nail, by which it may also be separated from the accompanying vein. On the right side great caution must be used, on account of the position of the left vein beneath the artery and the right to its outer side. In the later stages of the operation, the patient should be turned on his sound side in order to prevent the intestines from falling over and pressing the peritoneum into the wound.

Results.—Writing in 1852, I stated that when we look at the depth at which this artery is situated, its great size, and proximity to the centre of the circulation, and consider the force with which the blood rushes through it, we cannot but be struck with the success which has attended its ligature.

Of 17 cases in which it had then been tied, 8 were cured, and 9 died; in 11 of the cases the ligature was applied for aneurism, and of these 7 recovered. The 4 that died perished rather from the magnitude and extent of the disease than from the effects of the operation; and it is remarkable, as showing the power of the anastomoses in maintaining the vitality of parts, that in no instance did gangrene ensue. Since this period the operation has been performed many times, but with much less satisfactory results. Stephen Smith, of New York, published the statistics of this operation in 1860, giving the details of 32 cases; of these, he says, 25 died and only 7 recovered. I think the numbers should be 24 and 8; and in one case Bushe's, the patient, an infant, died two months after the operation, the ligature having contracted and the artery being occluded and thus the deligation having succeeded. Garlt, of Berlin, in reproducing Smith's tables, adds 2 cases, both fatal. To these must be added also a fatal case by Dugna, of Charleston, and five in which the operation has, within the last few years, been performed in this country; once by Bickersteth, of Liverpool, successfully; once by Hargrave, of Dublin, whose patient died on the seventy-third day after the operation, of gangrene of the foot and profuse discharge from the wound; and once by Maunder, the patient, a man forty years of age, dying on the sixth day from gangrene of the lower extremity; by Marrant Baker in a youth of 17, from hemorrhage from a branch of the internal iliac, consequent on ulceration produced by sacro-iliac disease—fatal on the day following the operation. During the American War the operation was performed in 5 cases, all unsuccessful. These cases increase the total number to 44, of which 9 recovered and 35 died; in 9 of the cases the peritoneum was wounded, and of these 5 proved fatal. Of 19 cases in which this vessel was tied for hemorrhage, 18 proved fatal; the majority of the recoveries took place after operation for aneurism—which constituted about half of the cases.

The **Old Operation** has been performed in more than one case of iliac aneurism when from special circumstances it was not possible to tie the artery above the sac. In Syme's well-known case the sac was laid open and three ligatures applied, which were believed to include the external, internal, and common iliac arteries. The patient practically recovered, but died of puerperal fever some months after, before leaving the hospital. The post-mortem examination showed that the ligatures had been placed on the external iliac only. Sir Astley Cooper attempted the same operation in the case in which he subsequently tied the aorta. Heath laid open the sac of an iliac aneurism which had been opened by mistake for an abscess before being admitted into University College Hospital. The external iliac was tied from within the sac, but the patient died from secondary hemorrhage. The old operation can only be performed when it is possible to compress the aorta above the sac; and consequently, as Holmes points out, an attempt should be made to effect a cure by compression before so dangerous an operation is attempted.

Treatment by Compression has been successfully applied to aneurism of the iliac arteries. The compression must be applied to the aorta by means of Liston's tourniquet, as in the treatment of aneurism of the abdominal aorta (p. 242). A considerable number of cases have now been cured by these means. They have already been referred to when treating generally of the subject of compression of the arteries for the cure of aneurism. Murray insisted on the importance of complete arrest of the circulation in these cases, so that not the slightest current of blood should pass through the sac. One of his cases was cured in three quarters of an hour. One of Heath's (of Newmarket) consolidated in twenty minutes. Lawson in one case applied two tourniquets—one to the abdominal aorta, the other to the femoral below the sac. The abdominal tourniquet had to be removed at the end of twenty

minutes, owing to collapse and vomiting; the femoral one was maintained in position. When the abdominal compressor was removed the pulsations had already diminished, and at the end of four hours they ceased; the patient making a good recovery. Holmes has collected 10 cases of iliac or ilio-femoral aneurism, treated by this method; of these, 7 were cured, and in 3 the treatment failed. These 3 afterwards underwent ligature of the artery leading to the sac—in one case the abdominal aorta—and all died. These statistics clearly show that no operative treatment is justifiable, except after the failure of compression.

Ligature of the Aorta.—It is impossible not to contemplate with admiration the man whose mind was the first to conceive, and whose hand was the first to carry out, the determination to apply a ligature to the abdominal aorta; and who, guided by pathological observation and physiological experiment, ventured to arrest at once the circulation through the main channel of supply to the lower half of the body, trusting to the collateral circulation for the maintenance of the vitality of the parts thus suddenly deprived of blood. Sir A. Cooper was the first to place a ligature on the aorta, in 1817. Since that period the operation has been six times performed for aneurism; viz., by James, of Exeter; by Murray, at the Cape of Good Hope; by Monteiro, at Rio Janeiro; by South, of London; by McGuire, of Richmond, U. S.; by Stokes, of Dublin; and once, in circumstances which will be presently described, by Czerny, of Vienna.

TABLE OF CASES OF LIGATURE OF ABDOMINAL AORTA
FOR ANEURISMS.

SURGEON.	SEX.	AGE.	DATE.	NATURE OF ANEURISM.	OPERATIONS.	RESULTS.
1. SIR A. COOPER.	m.	35	1817	Diffused inguinal.	Incision through peritoneum	Death in 40 hours.
2. JAMES.	f.	41	1829	External iliac	Distal liga- ture distal peritoneum opened	Death in a few hours
3. MURRAY.	m.	...	1834	Inguinal.	Aorta tied behind peritoneum	Death in 24 hours
4. MONTEIRO.	m.	..	1842	Diffused inguinal	Aorta tied behind peritoneum	Death on 10th day
5. SOUTH.	m.	28	1856	Common iliac	Aorta tied behind peritoneum	Death in 42 hours.
6. MCGUIRE.	m.	30	1868	Lower part of aorta. Both com- mon iliacs, and left external iliac	Aorta tied behind peritoneum	Death in 12 hours
7. W. STOKES.	m.	70	1869	Iliac.	Aorta tied behind peritoneum	Death in 18 hours

In Sir A. Cooper's case, the inguinal aneurism had burst, and the aorta was tied about three-quarters of an inch above its bifurcation, by making an incision three inches in length through the abdomen, a little to the left of the umbilicus, the fingers being passed between the convolutions of the intestine, and the peritoneum covering the artery being scratched through. The patient survived forty hours. James ligatured the aorta much in the

same way as Sir A. Cooper did, in a case in which he had previously attempted the distal operation for an inguinal aneurism; but without success, the patient speedily dying. Murray ligatured the vessel by making an incision on the left side, in front of the projecting end of the tenth rib, and carrying it downwards for six inches to the anterior superior spine of the ilium. The parts were then carefully divided to the peritoneum, which was separated from the iliac fossa and the psoas muscle, when, with great difficulty, and by scratching with the end of an elevator and the finger-nails, room was made for the passage of the ligature round the artery, which was tied three or four lines above its bifurcation. The patient died in twenty-three hours. The most interesting case on record is that by Monteiro, who tied the aorta for a large false aneurism on the lower and right side of the abdomen; here the incision was made much as in Murray's case, and the artery ligatured with great difficulty. The patient lived till the tenth day, when he died of secondary hemorrhage. In South's case, the aorta was tied behind the peritoneum by an incision on the left side of the abdomen. The patient died in forty-three hours. McGuire's patient had an aneurismal tumor of the size of a goose's egg in the left iliac region. Digital pressure near the umbilicus was attempted, but could not be done. The operator's intention was at first to tie the left common iliac artery; but, finding the disease more extensive than he expected, he enlarged the incision and tied the aorta. The sac burst during the manipulation necessary to reach the aorta, and about a pint of blood was lost. The patient died in eleven hours. Stokes compressed the aorta with a silver wire passed round it in the way of a ligature. He made a crescentic incision five and a half inches in length in the left side of the abdomen, extending from an inch below the tenth rib to the middle of Poupart's ligament. The abdominal muscles and fascia transversalis were then incised, and the peritoneum exposed and drawn out of the iliac fossa. It was accidentally, but only slightly wounded. The patient being turned on his right side, the arteries and aneurism were exposed, and the wire passed by means of an aneurism-needle round the aorta immediately above its bifurcation. The patient died in twelve hours. Perhaps the most interesting point in this remarkable case is the fact of the pulsation returning in the left sound femoral artery nine hours after the operation, showing how rapidly the collateral circulation can be reestablished. Czerny's case scarcely belongs to the present category, but may be mentioned here. The patient was a French soldier, the upper part of whose thigh had been shattered by a ball during the Franco-German war. Secondary hemorrhage occurring, Czerny tied the common femoral, and also the superficial femoral below the origin of the profunda. This arrested the hemorrhage for a time; but in six days it recurred. Czerny then tied the common iliac; but, as the hemorrhage continued, he thought that he had tied the external iliac, and proceeded to apply another ligature--which he placed by mistake on the aorta. The patient survived twenty-six hours. In this case too, twenty-two hours after the operation, the injured limb was cold and as if dead, while the opposite limb was warm, and retained sensation and motion. In this operation, there are not only all the dangers attendant upon the ligature of arteries of the first magnitude, but also the risk of producing fatal peritonitis, whether the abdomen be cut through, or the vessel sought for by stripping up the peritoneum from the iliac fossa; and it appears to me that a patient suffering from so large an inguinal aneurism as to justify ligature of the aorta, would have a better chance of recovery, or rather of prolongation of life, by the adoption of proper constitutional treatment, together with pressure upon the tumor and the distal ligature or compression of the artery. Lister's aortic compressor might be applied in such cases, so

SPECIAL ANEURISMS.

moderate the flow of blood. Should the operation be again attempted, it is probable that the incision adopted by Sir A. Cooper would be the safest, as the danger of peritonitis is much less under the present mode of treatment.

ANEURISM OF THE INTERNAL ILIAC AND ITS BRANCHES.—Aneurism of the *Trunk of the Internal Iliac Artery* is extremely rare. The only case with which I am acquainted is one related by Sandifort. The three principal branches of this artery—the *Gluteal*, the *Sciatic*, and the *Pubic*—have all occasionally, though rarely, been found affected by this disease. Of these branches the gluteal has been most frequently found aneurismal, the sciatic next, and the pubic least frequently; indeed, I am acquainted with only one instance of aneurism of this vessel. It is the preparation 1701 in the Museum of the College of Surgeons; and it exhibits an aneurism of the trunk of the artery nearly an inch in diameter, full of laminated clot.

Aneurisms of the Gluteal and Sciatic Arteries may be either traumatic

or spontaneous. The University of Hanover, has published with comments, in the *Archiv für Chirurgie*, a series, the records of thirty-five cases of gluteal and sciatic aneurisms, to which must be added a case of gluteal aneurism described by Scarpa of Naples, and one by Bickersteth, of Liverpool. In twenty-seven cases the aneurism was distinctly gluteal; and in six distinctly sciatic. Of the gluteal aneurisms, and two of the sciatic, were of traumatic origin. Thirteen gluteal and four sciatic aneurisms were spontaneous. The gluteal aneurism has been generally found situated at the upper part of the greater sciatic notch; but may extend over a large portion of the buttocks. The sciatic aneurism lies more deeply; and a portion of the sac may be within the pelvis. The size of these aneurisms varies from a slight swelling to a tumor as large as a child's head. In almost all the recorded cases there has been a strong pulsation, isochronous with the heart's beat; and whirring and humming murmurs are heard on auscultation. There is almost always pain in the tumor itself and in the course of the sciatic nerve, which may be followed by paralysis of the parts supplied by it.

The affections with which these aneurisms are most likely to be confounded are abscesses, soft sarcomata, cysts, and sciatic hernia. The diagnosis is sometimes difficult; thus Guthrie ligatured the common iliac artery for a large pulsating tumor in the gluteal region, which presented all the characters of aneurism, but which proved, on the death of the patient eight months after the operation, to be a sarcoma.

Gluteal aneurisms have on several occasions been opened by mistake for abscesses. According to Holmes, this accident has most frequently happened when the aneurism has been more or less diffused, and in such cases it suggests that the aspirator should be used to render the diagnosis certain.

In the *Treatment*, various methods have been employed. *The sac has been laid open* and the gluteal artery tied in five cases, all of which recovered. In another instance, after laying open the sac, the aneurism (gluteal) was found to extend into the pelvis; and the internal iliac artery was tied, with a fatal result. *Ligature of the internal iliac artery* has been performed in eleven cases, six of which recovered. *The common iliac artery* has been tied in three cases, all of which proved fatal. *Injection of the perchloride of iron* has been used in six cases; four recovered, one died, and in one the result is not known. *Ligature of the sciatic artery* without opening the sac has been performed in two cases, one of which recovered. Spontaneous recovery is reported to have occurred in one case.

Ligature of the Internal Iliac.—This vessel was ligatured for the first time in 1812. The operation was performed by Stevens, of St. Cruz, on a

who suffered from an aneurism of the nates, supposed to be of the artery, but found after death three years subsequently to take it from the sciatic. Stephens in this case made an incision five inches on the left side of the abdomen, carefully dissected through the parietes, freed the peritoneum from the iliac fossa, turned it on one side, together with the ureter, and passed a ligature round the artery without much difficulty. Since that time the operation has been done twenty times; in six with success, by Arndt, White, Mott (who accidentally wounded the external iliac), Syme, Morton, and Gallozzi; in fourteen cases unsuccessfully, Kinison, of York (whose patient died, on the nineteenth day, of secondary hemorrhage), by Bigelow, Torracchi, Ciancone, Porta, Landi, Kimball, Mer, Thomas, J. K. Rodgers, and Higginson; and three times by me in the American Civil War.

Success that has hitherto attended this operation is certainly remarkable when we take into consideration the depth at which the artery is situated and its great size; it must, I think, be accounted for by the fact that, although it places the patient runs the ordinary risks attendant on the ligature of larger pelvic arteries from the exposure and handling of the peritoneum, yet he is saved the danger resulting from the supervention of gangrene, the anastomosis between its branches and that of the neighboring arteries being so free, and the course traversed by the blood so short, that no interruption can arise in the maintenance of the collateral circulation.

The steps of the operation necessary for the exposure of the internal iliac are precisely analogous to those requisite for the ligature of the common trunk. When the vessel is reached, it must be remembered that both the external and internal iliac veins are in close relation to it; the one being on the outer side, the other behind it. As these vessels are large, and their proximity, it is necessary that they should be separated by the finger-nail, or the flat end of the aneurism-needle, before the ligature is passed round the artery. Care must be taken also not to put the vessel too much on the stretch by pulling the ligature, lest the ilio-lumbar artery be ruptured. There is a risk of including the ureter which crosses the artery internally, as it adheres firmly to the peritoneum and is pushed on one side with it. The length of the artery varies much, usually ranging between one and two inches, and as when it is short it has a tendency to be placed deeply in the pelvis, it would, I think, be more prudent, and occasion less chance of secondary hemorrhage, for the Surgeon to ligature the common trunk.

FEMORAL AND POPLITEAL ANEURISMS.

I have, in the preceding section, considered aneurisms affecting the femoral artery, which are by no means unfrequent. Aneurisms of the thigh are rare; but those in the ham are very commonly encountered. Thus, 551 cases of aneurism recorded in the British medical journals of the last century. Crisp has found that 137 affected the popliteal, and only 66 the femoral artery. Of these 66, 45 were situated either in the groin or in the thigh, and 21 only were truly femoral or femoro-popliteal. One of the differences in the frequency of the occurrence of aneurism at different parts of the vessel, may be accounted for by attention to its anastomoses. In looking at the main artery of the lower extremity, from Poupart's ligament to where it terminates in the anterior and posterior tibials, we see that it may be divided in relation to the muscular sheath that surround it, into three principal portions: 1. That which is between Poupart's ligament and the inner margin of the sartorius, which may be considered *inguinal*; 2. That which intervenes between

this point and the aperture in the adductor tendon, and which may be considered *femoral*; and, 3. That division of the vessel which corresponds to the ham, and which may be considered *popliteal*. Of these three divisions, the first and last are comparatively superficial, and, being unsupported by muscle, readily expand; while the central portion of the artery is closely surrounded on all sides by muscular masses, and is very unlikely to be dilated into an aneurismal tumor. We find, also, that the inguinal portion of the vessel is closely and firmly invested by a dense and resistant fibro-areolar sheath, and is well supported by the fascia lata; whilst in the popliteal space the artery is surrounded merely by the ordinary areolar sheath, and receives no aponeurotic support. This difference in the connections of these two parts of the vessel may, to a certain extent, explain the greater frequency of aneurism in the ham than in the upper part of the thigh.

ANEURISM OF THE DEEP FEMORAL ARTERY is of extremely rare occurrence; indeed, I am acquainted with five cases only. One of these occurred

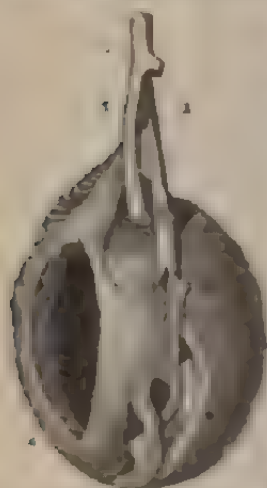

Fig. 489. Aneurism of a Femoral Artery.

1. Common femoral.
2. Superficial femoral.
3. Deep femoral.
4. Adductor tendon.

in a young man under my care in University College Hospital, in 1870. There was a large tumor at the upper part of the thigh, over which lay the superficial femoral artery, pulsating freely. The disease was cured by compression of the common femoral artery, hydrate of chloral being given to relieve pain. Another case is recorded by Bryant as having occurred in the practice of Cook at Guy's Hospital. The aneurism was situated at the origin of the deep femoral artery; the external clasp was tried, but the patient died nine weeks after the operation. Fig. 489 is taken from a patient who died of pneumonia shortly after admission into University College Hospital. On examination after death, a large tumor of the thigh, which had not been very closely examined during life, proved to be a circumscribed mass apparently arising from rupture of a perforating artery, most probably the circumflex artery of the femur. Univ. Coll. Museum, 12741.

Two cases are recorded by P. Marshall and J. Wilson. In the case which was under my care in the Hospital, the disease was recognized by the following signs, which are characteristic of it.

1. A large tumor extended from three inches below the inguinal ligament to the middle of the thigh, raising and slightly separating the adductor tendon.

2. All the ordinary aneurismal signs were present, the most marked being a peculiarly loud and harsh systolic murmur.

3. The superficial femoral artery could be felt pulsating over the tumor and upper aspect of the tumor, but clear of it.

4. The position of the popliteal and its divisions could not be felt.

5. The aneurismal area ceased on compressing the common femoral artery and resumed on removing the pressure.

The case was cured when an aneurism of the deep femoral artery can be cured, and in this case it was a perforating artery of the femur. The diagnosis must be left to the surgical tact of the practitioner.

In this case the case was recorded as an aneurism of the profunda but examination of the preparation shows it to be one of a perforating artery.

In the *Treatment* of these aneurisms, the Surgeon has the choice of three methods, viz. compression in the groin, and ligature of the external iliac, or of the common femoral. If the common femoral ever should be ligatured for aneurism, this appears to me to be the case best suited for it. But the choice between the ligature of this artery or of the external iliac must in a great measure depend upon the Surgeon's judgment as to the relative expediency of either operation, and on the height to which the aneurism extends up the groin. But neither artery should be ligatured until compression has been fairly tried and has failed. This may be done digitally or by Cartes's instrument, where the artery passes over the brim of the pelvis. It is especially likely to succeed in aneurism of the profunda, owing to the shortness of the trunk and the way in which it breaks up into many anastomosing branches. Hence there is not a free current of blood passing from one large vessel of entry to another of exit, but, as it is broken up and has to filter out through a number of minor vessels, its coagulation may readily be brought about. In the case treated by me, compression effected a cure in twenty-four hours, though the aneurism was very large and active.

ANEURISMS OF THE SUPERFICIAL FEMORAL AND POPLITEAL ARTERIES.—These occur commonly about the middle period of life, and are almost invariably met with in males, being at least twenty times more frequent in them than in women. Both sides are affected with equal frequency, and occasionally at the same time. According to Crisp, sailors would appear to be more liable to this variety of the disease than any other class. These aneurisms are most frequently sacculated; in the ham they are always so, but in the thigh they are sometimes tubular.

Symptoms.—The symptoms of **Femoral Aneurism** present nothing peculiar; the tumor usually enlarging with considerable rapidity, with all the characteristic signs of the disease, and assuming a pretty regular ovoid shape. **Popliteal Aneurism** usually commences with stiffness and a good deal of pain about the ham and knee, which I have more than once seen mistaken for rheumatism; in fact, so commonly does this happen, that the Surgeon should never fail to pass his hand behind and examine the ham in every case of persistent "rheumatic" pain in the knee. There is also a difficulty in straightening the limb, which is generally kept semiflexed. The tumor increases usually with great rapidity, and has a great tendency to become diffuse; these conditions will, however, materially depend on the side of the artery from which it springs. When it arises from the anterior aspect, next the bone, it increases slowly, being compressed by the firm structures before it. In this case, however, there is the great danger that, by its pressure upon the bones and knee, it may give rise to caries and destruction of the joint. When it springs from the posterior part of the artery, where it is compressed, it increases rapidly, and may speedily become diffuse. The rupture of an aneurism in this situation may take place in two directions. If it be femoral-popliteal, it may give way into the general areolar tissue of the thigh, the blood diffusing itself as high, perhaps, as Scarpa's triangle. When it is confined to the ham, it may give way either under the integuments, and into the superficial structures of the limb, or else under the deep vessels of the leg, where it will compress the posterior tibial nerve and artery. In all cases, the diffusion of popliteal aneurism is likely to be followed by gangrene.

Diagnosis.—The diagnosis of popliteal aneurism has to be made from abscesses, from torus enlargements, and from solid tumors. In distinguishing it from *chronic abscess*, no serious difficulty can well be expected; but it may happen that, when an aneurism has suppurated, considerable difficulty arises in determining its true nature—whether it be merely an

oblique and of the transversalis upwards and outwards. Both spatulae raise the peritoneum. By clearing away a little loose areolar tissue, the artery can be exposed for one inch and a half or two inches without difficulty. It has the genital branch of the genito-crural lying on it, and it is crossed by the circumflex iliac vein a little above Poupart's ligament; the external iliac vein is to its inner side; these must be carefully avoided. The needle must be passed from the inner side not less than one inch above Poupart's ligament, so as to avoid the epigastric and circumflex iliac arteries. After the operation a drainage-tube may be inserted at the lower angle of the wound, and a catgut suture inserted in the divided tendon of the external oblique.

On comparing the two operations, it would appear that the principal disadvantage of Abernethy's is, that it is apt to leave a tendency to hernial protrusion, in consequence of the abdominal wall being much weakened by the free incisions that are necessary through the muscular planes; the great advantage attending it is, that the external iliac may be ligatured at any part of its course, and that, if requisite, the incision may be extended upwards, and the common trunk secured. In Sir A. Cooper's operation, the line of incision lies directly across the course of the epigastric artery, which, as well as the circumflex ilii, if it arise high, and the circumflex vein, which crosses the iliac artery at this point, and is often somewhat funnel-shaped, may be in danger of being wounded. The spermatic cord is likewise somewhat in the way in this operation. Dupuytren actually wounded the epigastric artery in one case; and Houston had much difficulty from the circumflex vein in another instance. This operation has also the disadvantage, that the incision upwards cannot be conveniently prolonged so as to deligate any portion of the vessel except that which lies immediately above the crural arch; but the peritoneum is less disturbed than in the other case, and there is less tendency to hernial protrusion afterwards. As a general rule, I think we may conclude that, in cases of spontaneous aneurism, in which it might, from the size of the tumor or the diseased state of the vessels, be found necessary to apply the ligature to a higher point than was intended before the operation commenced, it will be safer to have recourse to Abernethy's plan, modified as above described, for in this way we shall be able to ligature the vessel at any part of its course; whilst in cases of hemorrhage after amputation, or of traumatic femoral aneurism, in which the artery is not likely to be diseased, recourse should be had to Cooper's operation, more particularly if the patient be thin, and the abdomen flat.

In connection with the ligature of the external iliac artery, there are some practical points that deserve mention. Before the operation, the colon should be emptied by means of an enema, and the pubes shaved. The incision in the abdominal wall must be sufficiently extensive.

In Abernethy's method, modified as above described, there is no fear of wounding the epigastric unless the incision be carried too far at its lower end. The artery may be roughly said to run in a line drawn from a point at which the femoral artery crosses the brim of the pelvis to the umbilicus. In neither method of operating should the incision implicate the external ring, lest it give rise to a tendency to hernial protrusion. Care should be taken not to wound the peritoneum; for, although two patients in whom this was done by Post and Tait both recovered, yet it is of course a dangerous accident, and should, if possible, be avoided. The peritoneum must not be torn up more than is absolutely necessary, lest hemorrhage or subsequent peritonitis occur. In raising the peritoneum, care must be taken not to displace the artery which lies loosely in the subperitoneal tissue, and can be easily raised in the spatula, or pushed over the brim of the pelvis. The separation of the peritoneum is much facilitated by the Surgeon holding the

removed or turned on one side. The fascia lata is then divided, and the crural sheath exposed. This must be carefully opened over the artery, and the needle passed from the inner side. The femoral vein lies to the inner side, and the anterior crural nerve a short distance away on the outer side. The origin of the branches is very uncertain; the Surgeon must select that part of the vessel for ligature which is most distant from any branch.

The statistics of this operation are so unfavorable, especially when performed for aneurisms, and secondary hemorrhage has been so frequent and fatal an occurrence, in several cases requiring ligature of the external iliac for its arrest, that I do not think it is advisable to have recourse to this operation in preference to ligature of the external iliac; and it may be laid down as a rule in surgery, that in all those cases of aneurism that are situated above the middle of the thigh, in which compression has failed and sufficient space does not intervene between the origin of the deep femoral and the upper part of the sac for the application of a ligature to the superficial femoral, the external iliac should be tied.

Ligature of the Superficial Femoral.—The superficial femoral artery, in its course from the origin of the deep femoral to the aperture in the tendon

Fig. 491.—Ligature of the Superficial Femoral Artery.

of the adductor, is divided by the crossing of the sartorius muscle into two portions of unequal length, which have different relations to neighboring structures. The upper division of the artery, which lies above the anterior margin of the muscle, is of most interest to the Surgeon, as it is in this part of its course that it is invariably ligatured in cases of aneurism. It is true that John Hunter, in the operation which he introduced for popliteal aneurism, exposed and tied the vessel in the middle third of the thigh; but his example has not been followed by modern Surgeons, on account of the far greater difficulty in reaching the vessel here than in the first part of its course. The superficial femoral, where it lies in Scarpa's triangle, being

covered merely by the common integument, the superficial fascia and the fascia lata, may be reached by as simple an operation as any that the Surgeon has to perform for the ligature of the larger vessels. The line to the artery is taken as follows: The leg is flexed and the thigh rotated outwards. The Surgeon marks a point exactly midway between the anterior superior spine of the ilium and the symphysis pubis. From this he draws a line to the most prominent part of the inner condyle of the femur. The point selected for tying the artery must be about five inches below Poupart's ligament, as the ligature will then be at a safe distance from the profunda, the lowest branches of origin of that vessel being four inches below the ligament. The incision (Fig. 491) is made in the line above indicated, and should be from three to six inches in length, according to the amount of aneurismal sac. It must be so arranged that the point selected for the application of the ligature shall be in the middle of its length. The skin and superficial fascia having been divided, the fascia lata is exposed and opened to the same extent as the incision in the integuments; the muscular fibres of the sartorius now come into view. If the incision have been made too far inwards, it is possible that the adductor longus may be exposed instead of the sartorius, the latter is readily recognized by observing the direction of the fibres, those of the adductor being downwards and outwards, and those of the sartorius downwards and inwards. The edges of the wound in the fascia being held apart with blunt hooks, the sartorius is seized in the forceps and drawn outwards, the fibres of the areolar tissue surrounding it being touched with the edge of the scalpel, if necessary, until its inner edge comes into view. If the operation be performed a little higher than usual, or if the sartorius be feebly developed, its inner edge may come into view as soon as the fascia lata is divided. The edge having been found, the muscle must be turned outwards, and held on one side with a copper spatula. A little loose areolar tissue must then be cleared away from beneath it with the handle of the scalpel, and the sheath of the vessels comes clearly into view. The sheath must be cautiously opened, a small hole being made in it as in the diagram (Fig. 492). It must be remembered that after the fascial sheath common to the artery and vein has been opened, there is still the proper sheath of the artery to be divided before the ligature can be safely passed. The vein lies beneath the artery, and consequently the needle may be passed from the inner or outer side indifferently; it should be passed

Fig. 492. Diagram of the Left Femoral Artery at Apex of Scarpa's Triangle. s, sartorius; f, femoral sheath; a, artery.

unarmed, and then be threaded and withdrawn. Usually, no nerve is seen during the operation, but the internal saphenous occasionally comes into view, and must be avoided. After the operation a drainage-tube should be inserted in such a way that its end shall lie beneath the sartorius, and the wound is closed with sutures. The wound is then semiflexed, somewhat raised, and laid on its outer side and wrapped in soft flannel or cotton wool. The severe pain which is usually complained of about the knee after tightening the ligature may be relieved by a full dose of opium.

In this operation there are several points of considerable importance that require special attention. 1. The incision should be made directly in the guiding line of the artery, care being taken not to incline it inwards in the direction of the sartorius. 2. In cutting down upon the artery, the saphenous should be avoided, by taking care not to make the incision too far

It has, however, happened that the ligature has been placed three-quarters of an inch of the origin of the deep femoral, without serious consequences resulting. 5. The greatest care must be taken round the femoral vein, which lies behind the artery in the situation in which a ligature is usually applied. If the vessel is tied a little higher up, the vein will be towards the inner side, and then the needle is passed from within outwards. Wounding the vein is best avoided by carefully cleaning the artery; the white external coat must be thoroughly exposed, and while the needle is being passed the sheath should be pushed roughly on the stretch, the Surgeon holding the edge of the opening side from which he is passing the needle, while the assistant catches the other end in a pair of forceps and draws gently upon it. In passing the needle, its end should be kept very close to the artery, and made to round it. The vein is generally perforated by dipping the needle too far and losing the contact between it and the artery. When the needle is brought up on the outer side of the artery, a small portion of the sheath is sometimes pushed up by it; this must be torn by pinching it with the thumb and forefinger, when the needle may be carried round the vessel.

6. —Ligature of the femoral artery for popliteal aneurism is an operation that has been so frequently performed, that Surgeons seldom think of it as a case of this description, unless they present complications or of unusual interest or severity; hence, but little importance can be attached to any statistical deductions from reported cases as to the fatality of the operation, although they may serve as a rough estimate of the proportion maintained between the different accidents, such as hemorrhage, &c. etc., that follow it. That ligature of the femoral artery is attended with more success than that of any of the other large trunks can be no doubt. This is not only in accordance with the general experience of Surgeons, but is confirmed by the statistics of published cases, even making allowance for the probability of more of the unsuccessful cases having been recorded. Thus of 110 instances, collected by Mr. Jones, in which the femoral artery had been ligatured for popliteal aneurism, twelve are reported to have died: amongst these, four deaths were by secondary hemorrhage, three by gangrene, and the others by tetanus, chest-disease, &c. Higher rates of mortality are, however, reported by other authors; thus, Norris states that nearly one in four die after the operation. Hutchinson finds that of thirty-three cases operated on in 1845, five died from hemorrhage, five from gangrene, and five from tetanus. Holmes's statistics show that of 100 cases, 15 died.

as to moderate the flow of blood. Should the operation be again attempted, there is little doubt that the incision adopted by Sir A. Cooper would be the safest, as the danger of peritonitis is much less under the present modes of treatment.

ANEURISM OF THE INTERNAL ILIAC AND ITS BRANCHES.—Aneurism of the *Trunk of the Internal Iliac Artery* is extremely rare. The only case with which I am acquainted is one related by Sandifort. The three principal branches of this artery—the *Gluteal*, the *Sciatic*, and the *Pudic*—have all occasionally, though rarely, been found affected by this disease. Of these branches the gluteal has been most frequently found aneurismal, the sciatic next, and the pudic least frequently; indeed, I am acquainted with only one instance of aneurism of this vessel. It is the preparation 1701 in the Museum of the College of Surgeons; and it exhibits an aneurism of the trunk of the pudic nearly an inch in diameter, full of laminated clot.

Aneurisms of the Gluteal and Sciatic Arteries may be either traumatic or spontaneous.

Fischer, of Hanover, has published with comments, in the *Archiv für klinische Chirurgie*, the records of thirty-five cases of gluteal and sciatic aneurism, to which must be added a case of gluteal aneurism described by Gallozzi, of Naples, and one by Bickersteth, of Liverpool. In twenty-seven of the cases the aneurism was distinctly gluteal; and in six distinctly sciatic. Thirteen of the gluteal aneurisms, and two of the sciatic, were of traumatic origin, fourteen gluteal and four sciatic aneurisms were spontaneous. The gluteal aneurism has been generally found situated at the upper part of the great sciatic notch; but may extend over a large portion of the buttocks. Sciatic aneurism lies more deeply; and a portion of the sac may be within the pelvis. The size of these aneurisms varies from a slight swelling to a tumor as large as a child's head. In almost all the recorded cases there has been strong pulsation, isochronous with the heart's beat; and whirring and buzzing murmurs are heard on auscultation. There is almost always pain in the tumor itself and in the course of the sciatic nerve, which may be followed by paralysis of the parts supplied by it.

The affections with which these aneurisms are most likely to be confounded are abscesses, soft sarcomata, cysts, and sciatic hernia. The diagnosis is sometimes difficult; thus Guthrie ligatured the common iliac artery for a large pulsating tumor in the gluteal region, which presented all the characters of aneurism, but which proved, on the death of the patient eight months after the operation, to be a sarcoma.

Gluteal aneurisms have on several occasions been opened by mistake for abscesses. According to Holmes, this accident has most frequently happened when the aneurism has been more or less diffused, and in such cases he suggests that the aspirator should be used to render the diagnosis certain.

In the *Treatment*, various methods have been employed. *The sac has been laid open* and the gluteal artery tied in five cases, all of which recovered. In another instance, after laying open the sac, the aneurism (gluteal) was found to extend into the pelvis; and the internal iliac artery was tied, with a fatal result. *Ligature of the internal iliac artery* has been performed in eleven cases, six of which recovered. *The common iliac artery* has been tied in three cases, all of which proved fatal. *Injection of the perchloride of iron* has been used in six cases, four recovered, one died, and in one the result is not known. *Ligature of the sciatic artery* without opening the sac has been performed in two cases, one of which recovered. Spontaneous recovery is reported to have occurred in one case.

Ligature of the Internal Iliac.—This vessel was ligatured for the first time in 1812. The operation was performed by Stevens, of St. Croix, on a

negress who suffered from an aneurism of the nates, supposed to be of the gluteal artery, but found after death three years subsequently to take its origin from the sciatic. Stephens in this case made an incision five inches long on the left side of the abdomen, carefully dissected through the parietes, separated the peritoneum from the iliac fossa, turned it on one side, together with the ureter, and passed a ligature round the artery without much difficulty. Since that time the operation has been done twenty times; in six cases with success, by Arndt, White, Mott (who accidentally wounded the peritoneum), Syne, Morton, and Gallozzi; in fourteen cases unsuccessfully, by Atkinson, of York (whose patient died, on the nineteenth day, of secondary hemorrhage), by Bigelow, Torracchi, Camplone, Porta, Landi, Kimball, Altmüller, Thomas, J. K. Rodgers, and Higginson; and three times by Surgeons in the American Civil War.

The success that has hitherto attended this operation is certainly remarkable, when we take into consideration the depth at which the artery is situated and its great size; it must, I think, be accounted for by the fact that, although in these cases the patient runs the ordinary risks attendant on the ligature of the larger pelvic arteries from the exposure and handling of the peritoneum, yet he is saved the danger resulting from the supervention of gangrene; the anastomosis between its branches and that of the neighboring vessels being so free, and the course traversed by the blood so short, that no difficulty can arise in the maintenance of the collateral circulation.

The steps of the operation necessary for the exposure of the internal iliac artery are precisely analogous to those requisite for the ligature of the common trunk. When the vessel is reached, it must be remembered that both the external and internal iliac veins are in close relation to it; the one being to its outer side, the other behind it. As these vessels are large, and their coats thin, it is necessary that they should be separated by the finger-nail, or the blunt end of the aneurism-needle, before the ligature is passed round the artery, care must be taken also not to put the vessel too much on the stretch in applying the ligature, lest the ilio-lumbar artery be ruptured. There is little risk of including the ureter which crosses the artery internally, as it always adheres firmly to the peritoneum and is pushed on one side with it. As the length of the artery varies much, usually ranging between one and two inches, and as when it is short it has a tendency to be placed deeply in the pelvis, it would, I think, be more prudent, and occasion less chance of secondary hemorrhage, for the Surgeon to ligature the common trunk.

FEMORAL AND POPLITEAL ANEURISMS.

We have, in the preceding section, considered aneurisms affecting the groin, which are by no means unfrequent. Aneurisms of the thigh are much rarer; but those in the ham are very commonly encountered. Thus, out of 351 cases of aneurism recorded in the British medical journals of the present century, Crisp has found that 137 affected the popliteal, and only 66 the femoral artery. Of these 66, 45 were situated either in the groin or upper part of the thigh, and 21 only were truly femoral or femoro-popliteal. The reason of this difference in the frequency of the occurrence of aneurism in different parts of the vessel, may be accounted for by attention to its anatomical relations. In looking at the main artery of the lower extremity, in its course from Poupart's ligament to where it terminates in the anterior and posterior tibials, we see that it may be divided in relation to the muscular masses that surround it, into three principal portions: 1. That which is situated between Poupart's ligament and the inner margin of the sartorius, and which may be considered *inguinal*; 2. That which intervenes between

this point and the aperture in the adductor tendon, and which may be considered *femoral*; and, 3. That division of the vessel which corresponds to the ham, and which may be considered *popliteal*. Of these three divisions, the first and last are comparatively superficial, and, being unsupported by muscle, readily expand; while the central portion of the artery is closely surrounded on all sides by muscular masses, and is very unlikely to be dilated into an aneurismal tumor. We find, also, that the inguinal portion of the vessel is closely and firmly invested by a dense and resistant fibro-areolar sheath, and is well supported by the fascia lata; whilst in the popliteal space the artery is surrounded merely by the ordinary areolar sheath, and receives no aponeurotic support. This difference in the connections of these two parts of the vessel may, to a certain extent, explain the greater frequency of aneurism in the ham than in the upper part of the thigh.

ANEURISM OF THE DEEP FEMORAL ARTERY is of extremely rare occurrence; indeed, I am acquainted with five cases only. One of these occurred

Fig. 490.—False Aneurism of a Perforating Artery.

1. Common Femoral.
2. Superficial Femoral.
3. Deep Femoral.
4. Aneurism, cut open.

in a young man under my care in University College Hospital, in 1870. There was a large tumor at the upper part of the thigh, over which lay the superficial femoral artery, pulsating freely. The disease was cured by compression of the common femoral artery, hydrate of chloral being given to relieve pain. Another case is recorded by Bryant as having occurred in the practice of Cook at Guy's Hospital. The aneurism was situated at the origin of the deep femoral artery; the external iliac was tied, but the patient died nine weeks after the operation. Fig. 490 is taken from a patient who died of pneumonia shortly after admission into University College Hospital. On examination after death, a large tumor of the thigh, which had not been very closely examined during life, proved to be a circumscribed false aneurism apparently arising from rupture of a perforating artery, most probably the consequence of embolism (Univ. Coll. Museum, 1274). Two cases are recorded by P. Marshall and J. Watson. In the case which was under my care in the Hospital, the disease was recognized by the following signs, which are characteristic of it:

1. A large tumor extended from three inches below Poupart's ligament to the middle of the thigh, raising and slightly separating the adductor

muscles and the rectus femoris. 2. All the ordinary aneurismal signs were present in this tumor—the most marked being a peculiarly loud and harsh bruit, and a dry, forcible thrill. 3. The superficial femoral artery could be felt running over the anterior and inner aspect of the tumor, but clear of, and distinct from, it. 4. The pulsation in the popliteal and its division was strong and perfect. 5. All the aneurismal signs ceased on compressing the common femoral artery, and returned on removing the pressure.

The only disease with which an aneurism of the deep femoral artery can readily be confounded is pulsating sarcoma of the femur. The diagnosis from this must be left to the surgical tact of the practitioner.

* In former editions this case was described as an aneurism of the profunda but careful reexamination of the preparation shows it to be one of a perforating artery.

In the *Treatment* of these aneurisms, the Surgeon has the choice of three methods, viz. compression in the groin, and ligature of the external iliac, or of the common femoral. If the common femoral ever should be ligatured for aneurism, this appears to me to be the case best suited for it. But the choice between the ligature of this artery or of the external iliac must in a great measure depend upon the Surgeon's judgment as to the relative expediency of either operation, and on the height to which the aneurism extends up the groin. But neither artery should be ligatured until compression has been fairly tried and has failed. This may be done digitally or by Carte's instrument, where the artery passes over the brim of the pelvis. It is especially likely to succeed in aneurism of the profunda, owing to the shortness of the trunk and the way in which it breaks up into many anastomosing branches. Hence there is not a free current of blood passing from one large vessel of entry to another of exit, but, as it is broken up and has to filter out through a number of minor vessels, its coagulation may readily be brought about. In the case treated by me, compression effected a cure in twenty-four hours, though the aneurism was very large and active.

ANEURISMS OF THE SUPERFICIAL FEMORAL AND POPLITEAL ARTERIES.—These occur commonly about the middle period of life, and are almost invariably met with in males, being at least twenty times more frequent in them than in women. Both sides are affected with equal frequency, and occasionally at the same time. According to Crisp, sailors would appear to be more liable to this variety of the disease than any other class. These aneurisms are most frequently aneurysmal; in the ham they are always so, but in the thigh they are sometimes tubular.

Symptoms.—The symptoms of **Femoral Aneurism** present nothing peculiar; the tumor usually enlarging with considerable rapidity, with all the characteristic signs of the disease, and assuming a pretty regular ovoid shape. **Popliteal Aneurism** usually commences with stiffness and a good deal of pain about the ham and knee, which I have more than once seen mistaken for rheumatism; in fact, so commonly does this happen, that the Surgeon should never fail to pass his hand behind and examine the ham in every case of persistent "rheumatic" pain in the knee. There is also a difficulty in straightening the limb, which is generally kept semiflexed. The tumor increases usually with great rapidity, and has a great tendency to become diffuse; these conditions will, however, materially depend on the side of the artery from which it springs. When it arises from the anterior aspect, next the bone, it increases slowly, being compressed by the firm structures before it. In this case, however, there is the great danger that, by its pressure upon the bones and knee, it may give rise to caries and destruction of the joint. When it springs from the posterior part of the artery, where it is uncompressed, it increases rapidly, and may speedily become diffuse. The diffusion of an aneurism in this situation may take place in two directions. If it be femoro-popliteal, it may give way into the general areolar tissue of the thigh, the blood diffusing itself as high, perhaps, as Scarpa's triangle. When it is confined to the ham, it may give way either under the integuments and into the superficial structures of the limb, or else under the deep fascia of the leg, where it will compress the posterior tibial nerve and artery. In all cases, the diffusion of popliteal aneurism is likely to be followed by gangrene.

Diagnosis.—The diagnosis of popliteal aneurism has to be made from abscess, from bursal enlargements, and from solid tumors. In distinguishing it from chronic abscess, no serious difficulty can well be experienced, but it may happen that, when an aneurism has suppurated, considerable difficulty arises in determining its true nature—whether it be merely an

abscess or not. On such cases as these, the state of the circulation in the lower part of the limb will throw much light. *Bursal tumors*, often of large size and multilocular, are not unfrequently met with in the ham, but I have never found any great difficulty in determining their true nature, their elasticity and roundness, together with their mobility and want of pulsation, being sufficiently indicative of their character. The most serious diagnostic difficulty may arise from confounding solidified aneurisms of the ham with *solid tumors*, of a sarcomatous character, springing from the tibia and femur; and I have known one case of aneurism in this condition, in which amputation was performed on the supposition of its being a solid tumor (Fig. 447).

Treatment.—The treatment of femoral and popliteal aneurism may be conducted either by compression or by ligature of the vessel leading to the sac. As a general rule, for the reasons already stated, compression should be employed in preference to ligature; but cases do arise in which, from the failure of compression, or for other reasons, it becomes necessary to ligature the femoral artery.

The *Treatment by Compression* is peculiarly applicable to these aneurisms, and, indeed, it is to them that it has chiefly been employed. I need, therefore, say nothing special about it here, but would refer the reader to Chapter XLIII., page 155, for a description of the subject.

Flexion of the knee, which may be considered a modification of compression, is applicable to these cases also, either alone or in combination with compression of the main trunk. It is peculiarly applicable in those cases in which the aneurism is situate entirely in the ham (see page 166).

Ligature of the Common Femoral.—In looking at the femoral artery, it might at first be supposed that the common trunk, situated superficially between Poupart's ligament and the origin of the profunda, would be the most convenient situation for the application of the ligature; but experience has shown that deligation of the vessel here is by no means a successful operation, especially when undertaken for aneurism. This arises from the shortness of the trunk rendering it necessary to tie the artery in close proximity to the collateral branch that will constitute the most direct and immediate agent in the anastomosing supply—viz., the deep femoral, so that the internal coagulum would not readily form. In addition to this, a number of small inguinal branches, the superficial epigastric and circumflex ilii, the superior and inferior external pudic, and very commonly one of the circumflex arteries of the thigh, more especially the internal, arise from the common trunk in its short course; and these vessels, though small in size, constitute a source of great embarrassment to the Surgeon during the operation; for, if wounded near their origin, they bleed most furiously, and are a cause of considerable danger afterwards, by interfering with the proper plugging of the vessel. The ligature of the common femoral has, however, several advocates, more particularly in Ireland, where the operation has of late years been done nine times, for wound and aneurism, with six recoveries and three deaths. The successful cases were as follows: Porter, sen., three; G. H. Porter, one; Smyly, one; Macnamara, one. In the American war, however, the operation is reported to have been performed in eighteen cases with only four recoveries; and Barwell states that out of thirty-one cases in which the artery was tied for aneurism, hemorrhage occurred in eighteen, and of these twelve died.

The vessel may be reached by a vertical or a transverse incision; of these the former is preferable. The incision commences at Poupart's ligament, at a point midway between the symphysis pubis and anterior superior iliac spine, and is carried downwards in the line of the artery for about two inches; the skin, fat, and superficial fascia are divided, and the lymphatic glands

removed or turned on one side. The fascia lata is then divided, and the crural sheath exposed. This must be carefully opened over the artery, and the needle passed from the inner side. The femoral vein lies to the inner side, and the anterior crural nerve a short distance away on the outer side. The origin of the branches is very uncertain; the Surgeon must select that part of the vessel for ligature which is most distant from any branch.

The statistics of this operation are so unfavorable, especially when performed for aneurisms, and secondary hemorrhage has been so frequent and fatal an occurrence, in several cases requiring ligature of the external iliac for its arrest, that I do not think it is advisable to have recourse to this operation in preference to ligature of the external iliac; and it may be laid down as a rule in surgery, that in all those cases of aneurism that are situated above the middle of the thigh, in which compression has failed and sufficient space does not intervene between the origin of the deep femoral and the upper part of the sac for the application of a ligature to the superficial femoral, the external iliac should be tied.

Ligature of the Superficial Femoral.—The superficial femoral artery, in its course from the origin of the deep femoral to the aperture in the tendon

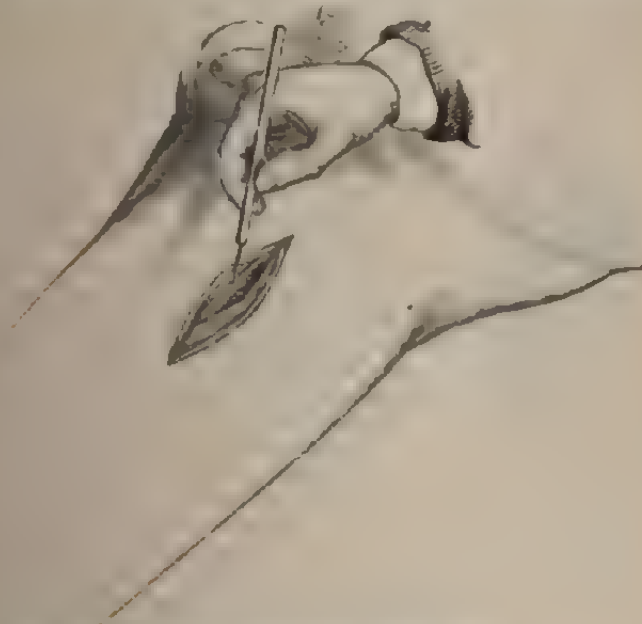

Fig. 491. Ligature of the Superficial Femoral Artery

of the adductor, is divided by the crossing of the sartorius muscle into two portions of unequal length, which have different relations to neighboring structures. The upper division of the artery, which lies above the anterior margin of the muscle, is of most interest to the Surgeon, as it is in this part of its course that it is invariably ligatured in cases of aneurism. It is true that John Hunter, in the operation which he introduced for popliteal aneurism exposed and tied the vessel in the middle third of the thigh; but his example has not been followed by modern Surgeons, on account of the far greater difficulty in reaching the vessel here than in the first part of its course. The superficial femoral, where it lies in Scarpa's triangle, being

covered merely by the common integument, the superficial fascia and the fascia lata, may be reached by as simple an operation as any that the Surgeon has to perform for the ligature of the larger vessels. The line to the artery is taken as follows: The leg is flexed and the thigh rotated outwards. The Surgeon marks a point exactly midway between the anterior superior spine of the ilium and the symphysis pubis. From this he draws a line to the most prominent part of the inner condyle of the femur. The point selected for tying the artery must be about five inches below Poupart's ligament, as the ligature will then be at a safe distance from the profunda, the lowest recorded point of origin of that vessel being four inches below the ligament. The incision (Fig. 491) is made in the line above indicated, and should be from three to six inches in length, according to the amount of subcutaneous fat. It must be so arranged that the point selected for the application of the ligature shall be in the middle of its length. The skin and superficial fascia having been divided, the fascia lata is exposed and opened to the same extent as the incision in the integuments; the muscular fibres of the sartorius now come into view. If the incision have been made too far inwards, it is possible that the adductor longus may be exposed instead of the sartorius, the error is readily recognized by observing the direction of the fibres, those of the adductor being downwards and outwards, and those of the sartorius downwards and inwards. The edges of the wound in the fascia being held apart with blunt hooks, the sartorius is seized in the forceps and drawn outwards, the fibres of the areolar tissue surrounding it being touched with the edge of the scalpel, if necessary, until its inner edge comes into view. If the operation be performed a little higher than usual, or if the sartorius be feebly developed, its inner edge may come into view as soon as the fascia lata is divided. The edge having been found, the muscle must be turned outwards, and held on one side with a copper spatula. A little loose areolar tissue must then be cleared away from beneath it with the handle of the scalpel, and the sheath of the vessels comes clearly into view. The sheath must be cautiously opened, a small hole being made in it as in the diagram (Fig. 492). It must be remembered that after the fascial sheath common to the artery and vein has been opened, there is still the proper sheath of the artery to be divided before the ligature can be safely passed. The vein lies beneath the artery, and consequently the needle may be passed from the inner or outer side indifferently; it should be passed

Fig. 492. Diagram of the Left Femoral Artery at Apex of Scarpa's Triangle, *s* sartorius; *f*, femoral sheath; *a*, artery.

unarmed, and then be threaded and withdrawn. Usually, no nerve is seen during the operation, but the internal saphenous occasionally comes into view, and must be avoided. After the operation a drainage-tube should be inserted in such a way that its end shall be beneath the sartorius, and the wound is closed with sutures. The wound is then semiflexed, somewhat raised, and laid on its outer side and wrapped in soft flannel or cotton wool. The severe pain which is usually complained of about the knee after tightening the ligature may be relieved by a full dose of opium.

In this operation there are several points of considerable importance that require special attention. 1. The incision should be made directly in the guiding line of the artery, care being taken not to incline it inwards in the direction of the sartorius. 2. In cutting down upon the artery, the saphenous vein should be avoided, by taking care not to make the incision too far

inwards. Any parallel venous branch that may be met with must be drawn on one side. 3. After the sheath has been opened, it will sometimes be found that a rather large muscular branch is given off from the artery at about the point where it was intended to ligature it: if so, this must be carefully avoided, as well as any small veins that cross the main trunk in this situation. 4. The ligature should not be applied less than four inches below Poupart's ligament, so that sufficient space may intervene between the origin of the deep femoral, which is usually from one to two inches below the crural arch, and the point deligated, to admit of the formation of a proper coagulum in the vessel. It has, however, happened that the ligature has been placed within three-quarters of an inch of the origin of the deep femoral, without any injurious consequences resulting. 5. The greatest care must be taken not to wound the femoral vein, which lies behind the artery in the situation in which a ligature is usually applied. If the vessel is tied a little higher than usual, the vein will be towards the inner side, and then the needle must be passed from within outwards. Wounding the vein is best avoided by thoroughly cleaning the artery; the white external coat must be thoroughly exposed, and while the needle is being passed the sheath should be put thoroughly on the stretch, the Surgeon holding the edge of the opening on the side from which he is passing the needle, while the assistant catches the opposite side in a pair of forceps and draws gently upon it. In passing the needle, its end should be kept very close to the artery, and made to circle round it. The vein is generally perforated by dipping the needle too deeply and losing the contact between it and the artery. When the needle is brought up on the outer side of the artery, a small portion of the sheath is sometimes pushed up by it; this must be torn by pinching it with the forceps when the needle may be carried round the vessel.

Results.—Ligature of the femoral artery for popliteal aneurism is an operation that has been so frequently performed, that Surgeons seldom think of recording cases of this description, unless they present complications or aspects of unusual interest or severity; hence, but little importance can be attached to any statistical deductions from reported cases as to the fatality of this operation, although they may serve as a rough estimate of the proportion maintained between the different accidents, such as hemorrhage, gangrene, etc., that follow it. That ligature of the femoral artery is attended with more success than that of any of the other large trunks can admit of no doubt. This is not only in accordance with the general experience of Surgeons, but is confirmed by the statistics of published cases, even without making allowance for the probability of more of the unsuccessful than successful having been recorded. Thus of 110 instances, collected by Crisp, in which the femoral artery had been ligatured for popliteal aneurism, only twelve are reported to have died; amongst these, four deaths were caused by secondary hemorrhage, three by gangrene, and the others by phlebitis, tetanus, chest disease, etc. Higher rates of mortality are, however, given by other authors; thus, Norris states that nearly one in four die after this operation; Hutchinson finds that of thirty-three cases operated on in London, ten were fatal, five deaths resulting from gangrene. Holmes's statistics, which are extremely valuable as being collected directly from hospitals and not from published cases, show very favorable results. Of eighty-seven cases in which the operation was performed for femoral or popliteal aneurism thirteen died and in three the operation failed to cure the disease, gangrene occurred twice, and suppuration of the sac not once. Of the deaths one was from smallpox, two from wound of the vein and phlebitis, three from pyæmia, one from gangrene and amputation, one from disease of the kidneys, and the rest from various other causes. Barwell has collected

also from hospital reports 67 cases occurring in the ten years 1870 to 1879 inclusive. Of these 10 died. Most of the deaths occurred, however, in the first half of this period, in which 32 cases were operated on, with 7 deaths and 2 amputations; while in the second half, out of 35 cases there were 3 deaths and no amputations. Barwell has also contrasted the results with reference to the various materials used as ligatures. He finds that in 14 cases silk was used; of these 3 died, 1 of rupture of an aneurism at the site of ligature, 1 of secondary hemorrhage and 1 of pyæmia, and in 1 case the aneurism relapsed. In 27 cases catgut was used, of these 6 died and 3 relapsed. Of the deaths, 1 arose from causes unconnected with the operation, 2 of secondary hemorrhage, and 2 after retying for relapse or aneurism at the site of ligature. In 4 cases the ox-aorta ligature was used successfully. The catgut used some years ago was somewhat uncertain in its quality, and in one of the cases in which secondary hemorrhage occurred, it was applied without antiseptic precautions, and consequently differed but little from the old silk ligature in its properties. It remains to be determined what form of ligature gives the best results—whether catgut prepared according to the later methods (*vide* vol. i. p. 124), carbolized silk, or the ox-aorta, applied in such a way as not to divide the inner and middle coats. There is little doubt that the low death-rate of the later period is due to improvement in the ligature and in the after-treatment of the wound, and there is every reason to hope that it will at least be maintained, and probably be further reduced.

Accidents.—**Wound of the Femoral Vein** is without doubt the most serious accident that can happen in the operation for ligature of the superficial femoral artery, and is one of which there is especial risk when recourse is had to this operation for aneurism; as in this disease the fine areolar tissue which naturally connects the two vessels often becomes thickened and indurated, in consequence of chronic inflammation extending upwards from the sac to the sheath of the vessels. It is best avoided by passing the needle in the way that has been already recommended, unarmed and without the employment of force. This accident is almost invariably fatal, there being but very few instances on record in which patients have survived it; death usually resulting from septic phlebitis, or the supervention of gangrene. The true cause of the fatal result in these cases was first pointed out by Hadwen, who showed that, when the vein is wounded by the aneurism-needle, it is transfixed at two points, between which the thread is drawn across; and when this is tied, a segment of the vein is necessarily included with the artery in the noose. It is this inclusion of the ligature within a portion of the vein, where it acts like a seton, and keeps up constant irritation, that occasions thrombosis and subsequent disintegration of the clot in the interior of the vessel; and it is consequently this circumstance, and not the mere wound of the vein, that determines the great fatality of this accident. Guided by this view, the treatment becomes obvious. It consists in removing the ligature at once, and thus, by taking away the source of irritation, converting the wound into a simple puncture of the vessel, which readily heals. The Surgeon should, therefore, as soon as the accident is perceived, withdraw the ligature, and, opening the sheath about half an inch up, reapply it to the artery there. The hemorrhage from the punctured vein readily ceases on the application of a compress.

The occurrence of **Secondary Hemorrhage** after the ligature of the superficial femoral is a troublesome accident, and one in which the Surgeon, to use Ferguson's expression, "will most assuredly find himself in an eventful dilemma," and in which it is necessary that his line of action should have been well considered beforehand, as he may not have much time to spare for

reflection when such an event takes place. In cases of this kind four lines of treatment present themselves, viz.: the employment of pressure; ligature of the vessel at a higher point; deligation of the bleeding artery in the wound; or amputation of the limb.

Pressure may be applied by placing a graduated compress of lint or compressed sponge over the bleeding orifice, and fixing it there firmly by a horse-shoe tourniquet. This mode of treatment, although extremely uncertain, occasionally succeeds; should it not do so, however, and bleeding recur a second time, it is useless to continue it, as experience has shown that the hemorrhage will continue until the patient is worn out.

Ligature of the superficial femoral at a higher point, or, if the artery have been tied too high for this, deligation of the common femoral or of the external iliac, presents itself as a probable means of arresting the hemorrhage. Such an operation, however, is fraught with danger, and has, I believe, invariably been followed by gangrene. It might at first be supposed that the limb would not be placed in a worse situation after the ligature of the external iliac, whether the superficial femoral had been previously tied or not; the anastomosing channels remaining the same in either case. But in reality this is not so; for, although the blood might find its way through the epigastric, the circumflex iliac, the gluteal, and sciatic arteries, into the deep femoral and its branches, yet from this point the difficulty of its transmission through the limb would be materially increased. If the superficial femoral be open, it serves as a direct and easy channel for the conveyance, to the vessels of the leg and foot, of the blood brought by the anastomoses. But when the superficial femoral is tied, this blood must find its way through a second chain of anastomosing vessels,—those intervening between the branches of the deep femoral and the articular arteries of the knee; and here the real difficulty would arise, its impulse not being sufficient to overcome the obstruction to its passage through these small channels, which might not improbably be still further obstructed by the pressure of the aneurism. Should the anastomosing circulation be sufficiently free to maintain the vitality of the limb, it is not improbable that the recurrent blood would escape from the distal side of the ligature, and thus keep up the hemorrhage exactly as in case of wound. It appears indeed that the femoral artery, in a case of secondary hemorrhage after the application of the ligature, is in very much the same condition as an artery which has been wounded, and in which the bleeding, having been suppressed for some days, has returned with violence: and certainly the best course for the Surgeon to pursue is the same practice that he would follow in the event of secondary hemorrhage occurring from a wounded vessel, viz., to cut down upon the bleeding part and apply a ligature to it. That such an operation is surrounded with difficulties cannot be doubted; yet none would present themselves that care and skill might not overcome. The Surgeon would certainly have to cut into a part infiltrated with blood, in which the different tissues could not readily be distinguished, and the vessel when reached would be found to be inflamed and softened; yet, by free dissection above and below the wound, a portion of it might at last be exposed, where its coats would hold a ligature; or should this not be found, the wound might be firmly plugged from the bottom with compressed sponge; or the bleeding aperture might be touched with the actual cautery. Should these means fail, it would be safer to amputate the limb, than to endeavor to arrest the hemorrhage in any other way.

Gangrene of the Limb is perhaps the most frequent source of danger after ligature of the femoral artery for popliteal aneurism. It seldom occurs unless the tumor be of considerable magnitude, have become diffused, or

otherwise interfere seriously with the circulation through the limb. I have, however, seen it follow the operation when the popliteal aneurism was not larger than an orange; but, in this case, there was much oedema and congestion of the limb before the operation; and, on examination afterwards, it was found that the popliteal vein had been obliterated by the pressure of the tumor. The gangrene, may, in some cases, be prevented by the treatment that has been pointed out at p. 445, vol. i. When it has fairly declared itself, there is necessarily no resource left but amputation, and this operation is sufficiently successful; for I find that of fourteen cases in which it was done, there were ten recoveries, and but four deaths.

The **Return of Pulsation in the Sac** after the operation for popliteal aneurism is by no means of frequent occurrence: yet it has been met with in some instances, and **Secondary Aneurism** also has been found in this situation. In these cases the patient should be put upon a careful dietetic plan, the limb be kept elevated and at rest, and direct pressure applied by means of a compress and bandage. In this way cures have been effected by Wishart, Turner, Briggs, and Liston. In conjunction with such treatment, or in the event of its not sufficing, the compression of the common femoral artery as it passes over the pubic bone would in all probability effect a cure. Should it not do so, and the tumor continue to increase, threatening to suppurate, or to occasion gangrene, amputation would be the sole resource.

If catgut be used, return of pulsation may be due to premature softening of the ligature. This is recognized by the presence of pulsation at the point at which the vessel was tied as well as in the sac. This is hardly likely to

take place if well-prepared gut be used, and the wound be kept perfectly aseptic. Should it happen before the wound is healed, it may be opened up again and a second ligature applied above the situation of the first. If the coats appear to have been damaged by the first ligature, the vessel may be tied on each side of the injured spot. In some cases in which absorbable ligatures have been used, the recurrent pulsation has appeared at a much later period in consequence of a restoration of the lumen of the artery. Should this happen, the artery may be safely tied in Hunter's canal, as was successfully done by C. Heath under these circumstances in University College Hospital.

Ligature of the Femoral Artery in the Middle of the Thigh (Hunter's Canal).—The point at which Hunter tied the artery in his earlier cases, was situated midway between the groin and the knee. At this point the artery lies in the angle formed by the vastus internus on the outer side, and the tendons of the adductor longus and adductor magnus behind. It is covered by a distinct fascia passing between these structures, forming with them the space known as Hunter's canal. The vein at this point lies to the outer side of the artery, and the long saphenous nerve enters the canal external to the vessels and crosses them superficially. The sartorius muscle covers the fascia closing in the canal. To tie the artery in this situation, the limb is placed in the same position as for the operation in Scarpa's triangle, and the same guiding line must be taken to find the artery, but the incision must not be made in this line, but one breadth internal to and parallel to it; otherwise the edge of the

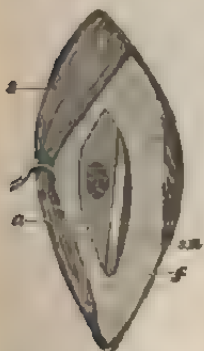

Fig 493.—Diagram of Ligature of the Left Femoral Artery in Hunter's Canal. *a*, sartorius drawn inwards; *f*, fascia closing the canal, opened freely; *a*, the artery, with a small opening in its sheath for the passage of the needle; *a*, long saphenous nerve.

sartorius is easily missed. The incision must be from three to four inches in length and its middle point must correspond to the middle of the thigh. The fascia lata is exposed, and opened, and the sartorius then comes into view. Its outer edge being found, it is pushed inwards, and held on one side with a copper spatula. The fascia closing the canal is then seen, and must be opened for about an inch and a half, thus exposing the sheath of the vessels (Fig. 493). If the saphenous nerve is seen, it must be drawn to one side with a blunt hook. The vein does not as a rule come into view, for as the limb is lying on its outer side it is beneath the artery and concealed by it. The sheath of the artery is then carefully opened and the needle passed from the outer side, the same precautions being taken as in the higher operation to avoid wounding the vein. The ligature should, if possible, be placed about one inch above the origin of the anastomotic branch. The errors that have to be guarded against in this operation, are, first, operating too low down. It must be remembered that Hunter's canal is situated midway between the groin and the knee. Secondly, if the wound be made too far out—in the guiding line of the artery instead of a finger's breadth internal to it—the outer border of the sartorius may be missed, and the vastus internus exposed instead. At this point there is usually an interval in the muscular fibres of the muscle that may be mistaken for the edge of the sartorius. The error is, as a rule, easily recognized by observing the direction of the muscular fibres, those of the vastus internus being directed downwards and outwards, while those of the sartorius are nearly vertical, slanting a little inwards. It is important that the fascia closing the canal should be opened freely, otherwise should pus form, it may burrow along the artery into the ham.

The **External Iliac Artery** may require to be tied in cases of popliteal aneurism when the superficial and common femorals are so diseased as not to admit of ligature. This occurred once to me. A gentleman who had lost the left foot and leg from spontaneous gangrene, became two years afterwards the subject of a large popliteal aneurism in the other leg. As compression failed, it was decided to tie the superficial femoral. On cutting down on the vessel the coats were found so diseased, the artery itself being cylindrically dilated and highly aneurismal, that the operation was abandoned; and, as the common femoral felt dilated and almost incompressible from calcification of its coats, it was decided to tie the external iliac. This I did with the able assistance of Sir W. Fergusson, at a rather high point, the vessel being somewhat dilated and calcified lower down. Pulsation recurred in the tumor a few hours after the operation, the collateral circulation being very free, and the patient died of secondary hemorrhage on the fifteenth day.

DOUBLE POPLITEAL ANEURISM.—In cases of this kind the artery has been occasionally ligatured with advantage on both sides, either simultaneously, or, with more safety, consecutively. But these cases appear to me especially adapted for the employment of pressure, so as to avoid that disturbance of the balance of the circulation which is certain to ensue when one vessel is ligatured, and which may act injuriously upon the opposite aneurism. When the popliteal aneurism is conjoined with a similar disease in the groin, ligature of the external iliac is the proper course to pursue, and will effect a cure of both affections.

DIFFUSED POPLITEAL ANEURISM.—When a *circumscribed* popliteal aneurism suddenly becomes *diffused*, the patient is seized with faintness or sickness, with pain, numbness, and a hot trickling sensation in the limb, the temperature of which falls at the same time that its bulk increases, whilst the integument assumes a white, slaving, mottled appearance, with more or less purplish discoloration. After a time as the tension increases inflammation is set up,

and the skin becomes red, hot, and oedematous, and the whole swelling may resemble in appearance a large abscess. Diffusion usually occurs after a circumscribed aneurism has existed in the ham for some weeks or months, and on the occurrence of some sudden exertion. In some cases, however, the disease appears to have been diffused from the very first, the coats having given way, and extravasation having taken place into the areolar tissue of the limb, without previous consolidation of the parts around the artery, or any attempt at the formation of a sac. In these cases the extravasation into the limb may either be conjoined with much oedema; or it may be confined to the areolar tissue of the ham, and to the upper and back part of the leg, or may extend downwards under the muscles of the calf. When the patient comes under the observation of the Surgeon, the tumor is found to be solid, elastic, and irregular, without pulsation or bruit; the limb oedematous, cold, and congested. The diagnosis of this form of aneurism is often extremely difficult, and there is great danger of confounding it with simple extravasation into the calf, with abscess, or, possibly, with malignant tumor of the leg.

Treatment.—The danger attending on popliteal aneurism is greatly increased by its becoming diffused. In these circumstances the ligature of the artery usually affords but a slender prospect of success, the collateral vessels being so compressed and choked by the pressure of the effused blood as not to admit of the circulation being carried on through them; hence in many of these cases, the only resource left to the Surgeon is to amputate the limb.

Amputation for Diffused Popliteal Aneurism.—The question of *Amputation* in cases of diffused popliteal aneurism is not very easily submitted to any very positive or definite rules, except where the impending gangrene is so evident as not to admit of doubt. There are, however, certain general considerations that may guide the Surgeon in deciding on this important point.

1. In some cases, the sac has either given way to a very limited extent, or else its walls, having become thin and expanded, are yielding rapidly under the pressure of the blood, becoming confused with the surrounding parts. Here we should ligature the artery without delay, for although it is but seldom that a limb can be saved when once the blood has become infiltrated into the general areolar tissue, yet it is possible that such a fortunate occurrence may happen.

2. In other instances the aneurism has not from the first been very distinctly circumscribed. It has followed the infliction of some mechanical injury, and in the course of a week or two has acquired a considerable size, without definite or distinct limitation, being solid or but little compressible. Such a case as this can scarcely be considered, strictly speaking, a diffused aneurism; but yet, if by *circumscribed* we mean that the blood is contained in a cyst with defined walls, it scarcely complies with such a definition the fluid blood being rather prevented from escaping widely by a temporary barrier of coagula entangled in the loose areolar tissue of the part, and the vessel being extensively ruptured or completely torn across. Here we are certainly justified in having recourse to compression or ligature, with a good prospect of success.

3. When the ham is occupied by a large rapidly increasing tumor, extending perhaps some way down the calf and up the thigh, and encroaching on the knee, the skin covering it being more or less discolored, there being no pulsation perceptible in the tibial arteries, and the veins of the limb being full and even somewhat congested, the foot oedematous and several degrees cooler than the opposite limb, the difficulty of coming to a decision is considerable.

In such a case as this, I think that the existence or absence of distensible pulsation is a circumstance of very great importance, and may serve to guide the Surgeon. If there be distinct impulse of a distending character, which can be arrested by compression of the femoral artery, with some diminution of the size of the tumor, it is evident that blood is being transmitted through the sac, and that this contains some fluid blood. In these circumstances it will, when the artery is tied, subside to a considerable extent, thus allowing more space for the conveyance of the collateral circulation, and it would be but right to give the patient the chance of preserving his limb by ligaturing the vessel.

It, however, the tumor have, from the very first time when it attracted the patient's notice, been more or less solid and incompressible; and, though it may at an early period have pulsed, if this pulsation have suddenly ceased, the aneurism at the same time having undergone rapid and great increase of bulk with much tension and lividity of the integuments, oedema and coldness of the limb, with a tendency, perhaps, to vesication and ulceration of the skin covering the tumor, there is no resource left but amputation.

It must, however, be borne in mind, that the aneurism may become diffused, and extensively so, without any very great change in the shape and size of the limb. It is only when the sac ruptures in such a position that the blood escapes into the general areolar tissue of the limb or under the skin, that much tension of the integuments and increase in the bulk of the part take place.

4. When a rupture occurs in a part of the sac that is more deeply seated, the blood is extravasated underneath the deep fascia of the leg, and is bound down by this; and disorganization of the interior of the limb may be the result, without much, if any, change in its bulk or in the color of the integuments, but with excessive, deeply seated pain. There must always be considerable risk, in such a case as this, of confounding the arterial disease with a solid tumor; and the diagnosis can be effected only by reference to the early history of the case, and more particularly to the existence or absence of pulsation at this period. Indeed, the existence or absence of pulsation in these cases is of the utmost importance in reference to the question of treatment. The pulsation may have ceased in a case of diffused popliteal aneurism, in consequence of the blood that has been extravasated being so confined and bound down by the fascia and muscles under which it is effused, that it compresses the mouth of the artery leading into the sac to such an extent as to arrest the passage of blood through it, either wholly or so that it enters in a feeble stream of insufficient force to communicate an impulse to the fluid that has been extravasated into the limb. This pressure may, as in the case of which an illustration has been given (Fig. 447), be confined to the deep parts of the limb, and not give rise to much, if any, general tension of it, the blood being confined below the deep fascia, where it communicates the sensation of a hard, solid, elastic tumor devoid of pulsation. Attention should consequently not be too exclusively directed to the state of general tension of the surface of a limb, as this is by no means necessarily an indication of the state of the parts beneath; but the Surgeon should look rather to the presence or absence of pulsation. If pulsation still exist, the blood continues to find its way into the sac, and most probably through it, the tension of the parts not having yet reached its maximum. If there be no pulsation, he may be sure that the entrance of blood into the diffused aneurism has ceased in consequence of compression exercised on the mouth of the artery leading to it, by the tense condition of the surrounding tissues resting on the mass of blood effused beneath them. In such a state of things as this, the vitality of the lower part of the limb can be maintained

only by the blood that may find its way through the anastomosing channels, and this may be sufficient for the purpose if the tension of the limb be not general, the extravasation being confined below the deep fascia. If surgical interference be delayed in such a case as this, the deep fascia will soon give way by over-distention and rupture, and the blood will be infiltrated into the general areolar tissue of the limb; and then, by compressing these collateral branches that have hitherto maintained a feeble circulation in it, will infallibly occasion gangrene. If, on the other hand, recourse be had to ligature of the main artery, the anastomosing circulation, which may have been barely sufficient to keep up a feeble vitality in the leg and foot will be so much interfered with that gangrene of the limb inevitably ensues. The only resource, therefore, that is left in these cases is to amputate at once, in order that the patient may be saved the shock and the constitutional disturbance occasioned by the setting in of mortification, as well as the pain and risk of a previous unnecessary operation.

5. When gangrene threatens, the leg and foot having become cold, the skin being either pale, tallowy, and mottled, or discolored, of a purplish hue, with perhaps vesications and much edema, whether the ligature have been previously applied to the femoral artery or not, or whatever the condition of the aneurism may be, whether circumscribed or diffused, the patient will stand a better chance of ultimate recovery by having the limb removed at once above the knee. The part at which amputation should be performed in these cases is a point deserving consideration. If the femoral artery have been ligatured, the thigh should be amputated on a level with the ligature, the artery being cut just above this. In this way the double risk which the patient would otherwise run of secondary hemorrhage from the seat of the ligature, as well as from the face of the stump, will be reduced to a single chance of hemorrhage from the stump. If the amputation be the primary operation, it should be done at the lower third of the thigh, provided the extravasation be confined to below the knee; or higher up, if the effused blood have extended above this joint.

Aneurisms of the Tibial Arteries are extremely rare, except as the result of wound, yet they are occasionally met with; and in the museum of St. George's Hospital is a preparation of a small aneurism of the posterior tibial. I have seen only one case during life—that of a man suffering from cardiac and renal disease, admitted into University College Hospital under my care for an aneurism of the anterior tibial at the lower part of the upper third of the right leg. The signs were well marked—pulsation forcible and eccentric, bruit loud. Compression was used without avail; and, as he was anasarctous, no other surgical treatment could be adopted. He left the hospital uncured.

The popliteal and tibial arteries sometimes require ligature for injury, but very rarely for disease. The operations may be briefly described here.

Ligature of the Popliteal Artery.—The popliteal artery may be tied at any part of its course. In the lower two-thirds it can be reached only by an incision in the line of the vessel. The external saphenous vein will be found in the subcutaneous tissue, and must be avoided. After dividing the fascia lata the internal popliteal nerve must be found and drawn to the outer side. The vein then comes into view and must be drawn out of the way, when the artery will be exposed lying deeply on the posterior ligament of the knee-joint. This operation is never undertaken except for a wound, and consequently must always be more or less of an informal character. In its upper third the vessel is reached most easily from the inner side. The guiding line for the incision is the posterior border of the tendon of the adductor magnus. The knee is flexed and the limb placed on its outer side, and an incision is

made from three to four inches in length parallel to the tendon of the adductor magnus and immediately behind it. Its upper extremity should correspond to the junction of the lower and middle thirds of the thigh. The skin and superficial fascia are divided, avoiding the long saphenous nerve if possible, and the deep fascia opened. The edge of the tendon of the adductor magnus, which forms the first rallying point in the operation, is then sought for. Some branches of the anastomotica magna are divided at this stage of the operation and require ligature. When the adductor tendon is found, the sartorius and gracilis and inner hamstring muscles are pushed backwards with the finger and held with a copper spatula. Care must be taken not to pass the spatula between the bone and the artery, which is surrounded in this situation by a considerable amount of loose fat. This fat being torn through, the artery is exposed without much difficulty. The vein and the internal popliteal nerve lie to the outer side and are not seen. The ligature should not be applied too near the superior articular branches.

- a. Posterior Tibial Artery.
- v. v. Venae Comites.
- n. Posterior Tibial Nerve.

Ligature of the Posterior Tibial Artery.—The line of direction of the posterior tibial artery is from a point about one inch below the knee, and equidistant from the two sides of the limb, to a point one finger's breadth behind the inner malleolus. The vessel may be tied at any part of its course, but it has rarely been undertaken as a formal operation except about the middle of the calf or behind the inner malleolus.

In the middle of the leg the posterior tibial artery should be tied only for a moment, and in such circumstances, as a rule, no regular operation can be performed, but an incision of sufficient length, taking the wound for its centre, must be made through the gastrocnemius and soleus parallel to their fibres, and, after these have been cut through, the deep fascia will be exposed. This must next be opened, when the artery will be found accompanied by its vein, and having the nerve to the outer side. From the depth at which the vessel is situated, and the free incisions that it is necessary to make through the soft parts it is extremely difficult to apply the ligature in this situation. In later steps of the operation may be much facilitated by flexing the leg at the thigh, and extending the foot, so as to relax the muscles.

The regular operation as performed on the dead body is rarely required on

the living. It is thus carried out. The limb is flexed and laid on its outer side. An incision is made four inches in length parallel to the posterior border of the tibia and about one inch behind it. The internal saphenous vein must be avoided if its situation can be ascertained. On dividing the deep fascia the edge of the gastrocnemius, if it has not fallen away to the outer side in this position of the leg, will come into view and is to be pushed to one side, exposing the surface of the soleus. This is next to be divided, the edge of the knife being now turned towards the posterior surface of the tibia. After cutting through about half an inch of muscular tissue a tendinous layer is exposed. This is the tendon of the deep surface of the soleus, and forms the first important rallying point in the operation. The tendon having been exposed in the whole length of the wound, it is picked up in the middle with a pair of forceps and carefully opened. The operator must now look to see if muscular fibres arise from its under surface. As a rule, no fibres arise from the internal half inch of the deep surface of the tendon, and if the incision through it be made at this point, the space between the deep and superficial muscles in which the artery lies is immediately opened. If the incision be more external, the fibres arising from the deep surface of the tendon must be divided before the proper space is opened. As soon as this is reached, the outer part of the soleus and the gastrocnemius must be drawn well outwards with a copper spatula, and the artery comes into view with a vein on each side, and the nerve most commonly to the outer side. The vessels are covered by a thin fascia, and lie on the fascia covering the deep muscles. Care must be taken in dividing the soleus not to wound this latter fascia, as should this happen the artery is easily lifted with the superficial muscles. The needle should be passed from the side on which the nerve lies.

The *posterior tibial artery behind the malleolus* is reached by making a semi-lunar incision about two inches in length, curving round the posterior and lower part of the malleolus, and one finger's breadth behind it. After dividing the skin and fat, the internal annular ligament comes into view. If the guiding line have been accurately adhered to, the artery will appear immediately the annular ligament is divided. It has a thick-walled vein on either side of it, which may be mistaken for the artery in a bloodless limb, unless it be carefully examined. The nerve lies behind and external to the artery, and the needle must be passed from behind. The most common error in tying this artery arises from keeping to the convex instead of to the concave side of the wound while deepening the incision. The deep parts of the incision thus gradually approach the malleolus, and the tendons are reached instead of the artery. The tendon of the tibialis posterior is that exposed, as it is most superficial. The artery must then be looked for behind this, and *immediately beneath the annular ligament*. If the dissection be carried on past the sheath of the tibialis posterior till the flexor longus digitorum comes into view, it will pass beneath the artery, which is then usually held out of the way in the posterior blunt hook, and is thus missed. The flexor longus pollicis lies so far behind the artery that it is scarcely possible to expose it.

The **Anterior Tibial Artery** may be tied in several situations, but, like the posterior tibial, it should not be ligatured in the upper or middle parts of the leg, except for injury. The difficulties of the operation are lessened as the ankle, where the artery becomes superficial, is approached. The line of direction of the anterior tibial artery is from the inner side of the head of the tibia to a point exactly midway between the two malleoli; and the course of the dorsal artery of the foot is from this point to the cleft between the first two toes.

In the upper third of the leg the artery lies deeply between the *tibialis anticus* and *extensor communis digitorum*, surrounded by veins, and having its nerve to the outer side. If it ever be found necessary to tie it in this situation, an incision should be made in the guiding line of the artery, from four to five inches in length. The deep fascia must be opened, and, if necessary, notched transversely. In the upper fourth of the limb the *tibialis anticus* arises from the fascia, which adds somewhat to the difficulty of finding the interval between the muscles. The first intermuscular space to the outside of the tibia is the one to be sought for. When it is found, the ankle must be flexed to relax the muscles, which are then held apart with copper spatulae. The artery may then be cleaned with a director, and the needle passed obliquely beneath it. In operating high up in the limb it is possible to slip into the space between the peronei and the *extensor digitorum*. This error is at once recognized by finding a distinct fibrous intermuscular septum, no such structure existing between the *tibialis anticus* and the *flexor digitorum*.

In the middle and lower thirds of the leg the artery will be found between the *tibialis anticus* and the *extensor proprius pollicis*; the latter muscle does not, however, reach the surface above the middle of the leg. The right space is found by keeping accurately to the guiding line of the artery, and, after the fascia is opened, taking the outer border of the *tibialis anticus* as the guide. The edge of the *flexor longus digitorum* is recognized by its rounded tendon, reaching considerably above the middle of the leg, with fleshy fibres joining it on the outer side.

The *Arteria Dorsalis Pedis* runs from a point midway between the two malleoli to the base of the space between the two first and second metatarsal bones, and may be felt pulsating in this line. It lies external to the tendon of the *extensor proprius pollicis*, and is crossed near its lower end by the internal belly and tendon of the *extensor brevis digitorum*. It is sometimes absent, and not unfrequently lies external to the line just mentioned. It is reached by an incision in the line of the artery, one inch and a half in length, the lower end of which corresponds to the base of the space between the first two metatarsal bones. The superficial and deep fascia being divided, the artery may immediately come into view. If it does not, the inner belly and tendon of the *extensor brevis* must be sought for, and its inner border followed till the long extensor is reached. If the artery is not seen passing beneath the tendon of the short extensor, that muscle must be forcibly pulled outwards and the vessel sought for beneath it. If it does not then come into view, it is probably absent. The termination of the anterior tibial nerve accompanies the artery when it is in its normal situation, and lies usually to the outer side of it.

The *Peroneal Artery* has been tied in rare cases for wound in the middle of the leg. It is found by making an incision about three inches in length on the posterior border of the fibula, which is the first "rallying point" in the operation. A thin tendinous layer, forming part of the origin of the *peroneus*, and sometimes a few fleshy fibres, are found attached to the bone. On dividing these, the *flexor longus pollicis* comes into view. This is cut carefully away from the posterior surface of the bone, and at its inner edge a tube of fascia is found, in which the artery lies between the *flexor pollicis* and *tibialis posticus*. This must be opened, and the veins comites separated with a director, after which the needle is easily passed.

DISEASES OF THE ORGANS OF SUPPORT AND MOTION.

CHAPTER XLVI.

INFLAMMATION OF BONE AND ITS EFFECTS.

GENERAL PATHOLOGY OF INFLAMMATORY AFFECTIONS OF BONE.

BEFORE proceeding to consider the diseases of bone as they present themselves to the practical Surgeon, it will be most convenient to describe the different pathological effects of inflammation on the separate structures of which bone is composed, viz., the periosteum, the medulla and the osseous tissue. The necessity for this arises from the fact that inflammatory affections are rarely limited to one of these structures. Thus inflammation commencing in the periosteum, if it last for any length of time, always produces more or less marked changes in the compact tissue beneath, and the cancellous tissue is never affected without the periosteum sooner or later taking part in the morbid process. I propose, therefore, to describe briefly the various effects of inflammation as they manifest themselves in the different structures of which a bone is composed, attaching as far as possible a definite name to each by which it can be referred to in the clinical description of the diseases as they occur in practice.

The process of inflammation in bone is essentially the same as in all other tissues—such modifications as exist being due solely to the structure of the affected part. In the chapter on Inflammation it was pointed out that in the more acute or destructive processes of inflammation the inflamed tissue becomes infiltrated with new cells, before which the original structures disappear. In the soft parts of a bone, the medulla and periosteum, this takes place exactly as in other tissues, but in compact bone this process is restricted and delayed by the density of the structure. The new tissue undergoes the same changes in bone as elsewhere; it may soften and break down into pus, it may undergo fatty degeneration and caseation, or it may undergo development, the product being as a rule osseous, instead of fibrous tissue, as in the soft parts. The chronic productive inflammatory processes which in the soft parts lead to fibroid induration or overgrowth of the connective tissue, when affecting a bone lead to the formation of new osseous tissue, but the process is essentially the same. As in other parts, the inflammation may end in death of the affected tissue. Acute infective inflammations also are met with, and the chronic processes associated with the development of tubercle are common. All these inflammations are identical in character with those already described as affecting the soft parts, such differences as exist being due solely to the physical peculiarities of the tissue implicated.

INFLAMMATORY PROCESSES IN THE PERIOSTEUM.—The periosteum is composed of two layers, the more superficial of which consists chiefly of white fibrous tissue; the deeper contains a large proportion of yellow elastic tissue. Forming part of the deep layer in immediate contact with the bone

is a stratum which contains numerous cells. In growing bone these have the ordinary appearance of the cells always found immediately preceding the formation of new bone, the so-called osteoblasts; they are granular and somewhat angular in outline. In adult bone these are represented by flattened cells, but they readily resume the form of osteoblasts under slight degrees of stimulation. The periosteum is extremely vascular, the vessels breaking up in it and entering the Haversian canals of the bone beneath, and numerous nerves may be traced in its structure. The effects of this structure in modifying the process of inflammation are obvious. The extreme vascularity of the membrane favors exudation, and the inflammatory products accumulate most abundantly in the deeper layers, and between them and the bone, beneath the denser fibrous layer. They penetrate also along the vessels into the Haversian canals. Owing to the abundant nervous supply and to the tension caused by the unyielding nature of the superficial layers of the periosteum, inflammatory exudation is often accompanied by very severe pain. Should the inflammation terminate in suppuration the vessels passing from the periosteum to the bone are destroyed, and death of a portion of the compact tissue may result. This is, however, by no means a necessary consequence, especially if the periosteum be separated only to a small extent, as the blood supply from the medulla is sufficient to maintain the vitality of the denuded bone. Sloughing of the periosteum as a result of inflammation is a somewhat rare occurrence owing to its abundant vascularity. Cessation of the inflammatory products is not common in periostitis, but is occasionally met with. Lastly, new bone is formed with great readiness in all chronic inflammatory processes in the periosteum, the mode in which it is developed being the same as in physiological growth, though wanting in regularity. The following are the names given to the various inflammatory processes occurring in the periosteum: (1) Simple Acute Periostitis; 2, Suppurative Periostitis, a. Simple and Localized, b. Infective and Diffuse; 3, Chronic Osteoplastic Periostitis; 4, Chronic Suppurative Periostitis; 5, Syphilitic Periostitis.

Simple Acute Periostitis.—This is most commonly the result of injury. The membrane is redder and thicker than natural. It separates easily, and as it is stripped off fine threads are seen passing from it into the bone; these are the vessels which are loosened by the exudation into the Haversian canals, and consequently draw out more readily. On section the swollen membrane presents a somewhat gelatinous appearance due to the infiltration of its structure with the inflammatory exudation; this is most marked in the deeper layers next the bone. Microscopic examination shows only the ordinary appearances of inflammation—distention and fulness of the vessels and numerous small round cells infiltrating the fibrous tissue, especially its deeper layers. Simple acute periostitis may end in resolution with a perfect return to the normal condition, or it may pass on to suppuration, but more commonly it becomes chronic and assumes the osteoplastic form.

Suppurative Periostitis, (a) Simple Acute Periostitis, resulting from injury occasionally terminates in suppuration. The pus forms between the membrane and the bone, and slowly perforates the fibrous layer. It shows but little tendency to extend beneath the periosteum or to separate it widely from the bone. It may be followed by death of the exposed portion of the compact tissue, but, as before stated, this is by no means necessary.

Infective Inflammation of the Periosteum is a much more serious affection. It occurs chiefly, if not exclusively, in young subjects. It terminates very early in suppuration and the pus diffuses itself widely, stripping the periosteum from the bone, sometimes throughout the whole extent of the diaphysis. When it reaches the epiphyses the inflammation and suppuration

extend in the growing tissue between them and the shaft, and thus in extreme cases the whole diaphysis may lie loose in the cavity of a vast abscess enclosed within the undestroyed fibrous layer of the periosteum; finally, this is perforated, and the pus diffuses itself amongst the surrounding tissues. In spite of the acuteness of the process, the periosteum very rarely sloughs, and if exit be given to the pus the intensity of the inflammation subsides and the periostitis assumes the osteoplastic form, new bone being abundantly deposited beneath it. Infective periostitis almost invariably leads to death of a considerable portion of the bone which has been laid bare by the separation of the membrane, but the extent that perishes does not necessarily correspond to that separated from its periosteum.

Osteoplastic Periostitis.—This is essentially a chronic process. It occurs as a consequence of the slighter forms of irritation, or as a sequel of acute inflammation. It is very frequently met with also as an accompaniment of more deeply seated inflammatory mischief, as of the medulla or cancellous tissue, and in the neighborhood of diseased joints. In young subjects it results from very slight sources of irritation, being then merely an exaggeration of the normal process of growth. In osteoplastic periostitis the membrane is thickened and more vascular than natural. It separates with some ease, and its under surface often feels gritty from small fragments of new bone that have come away with it. Beneath it and adherent to the compact tissue is the new bone formed as the result of the process. This may be arranged in smooth layers, parallel to the surface of the bone, in nodules or in pointed processes. When the nodulated or spiculated masses reach any considerable size they are frequently termed *osteophytes*. The new bone formed in the early stages of osteoplastic periostitis is soft and spongy, being traversed by large canals containing vessels surrounded by round cells. These canals are set at right angles to the surface of the bone. As recovery takes place the new bone is partly absorbed, the irregular nodular or spiculated masses are smoothed down and the remainder gradually increases in density, till it becomes indistinguishable from the compact bone beneath.

Microscopic examination of the parts involved in osteoplastic periostitis shows that the swollen membrane is infiltrated with small round cells, proportional in number to the acuteness of the process. In the deeper layers in contact with the newly forming bone, the cells assume the characteristic angular shape and granular appearance of osteoblasts. There seems to be a direct transition from the granulation-cells infiltrating the inflamed membrane to the osteoblasts. The new bone is formed subsequently in the same way as in normal ossification. Some of the osteoblasts are supposed to be transformed into a homogeneous intercellular substance, which becomes indistinctly fibrillated and subsequently calcified, the remaining cells forming the bone-corpuscles. The development of the inflammatory new growth into bone commences at the points most distant from the vessels, and gradually encroaches on them till they come to lie in channels surrounded by bone (Haversian canals). We have before seen that the same changes occur in the formation of callus in the repair of a fracture—vol. i. p. 504—but in these circumstances cartilage occasionally appears before the development of bone. This is never met with in osteoplastic periostitis arising from other causes.

Bellroth is of opinion that the new bone developed in osteoplastic periostitis is not always formed solely from the periosteum. That it is so in those cases in which the compact tissue beneath is dead is, of course, evident, but in other cases he believes that granulation-tissue sprouting out of the openings of the Haversian canals takes part in the process. In the union of fractures the callus is partly formed from the injured soft parts superficial to the periosteum.

Chronic Suppurative Periostitis is not common, but occasionally the periosteum is found separated from the bone by a small quantity of curdy pus such as is met with in chronic abscesses elsewhere. It is usually merely a secondary process, being dependent on some of the destructive changes to be subsequently described as commencing in the bone beneath.

Syphilitic Periostitis and Gummata of the Periosteum have been already described (vol. i. p. 1070).

Any localized chronic inflammatory swelling of the periosteum, whether simple or syphilitic, and whether accompanied by the formation of a new bone or not, is commonly termed a *node*.

INFLAMMATORY PROCESSES AFFECTING THE COMPACT TISSUE OF A BONE.—The compact tissue of bone is composed of lamellæ arranged for the most part concentrically around the Haversian canals. Beneath the periosteum the lamellæ lose their concentric arrangement and lie parallel to the surface. Between the lamellæ lie the bone-corpuscles in the lacunæ and from these the fine canaliculi pass through the bony tissue. The Haversian canals are narrowest near the surface, and gradually increase in size towards the deeper parts, so that the compact and the cancellous tissue gradually merge into each other without any sharp line of distinction between them. Each Haversian canal, except the very smallest, contains a small artery and vein, a flattened lymphatic vessel, and a pale nerve-fibre, surrounded by a small amount of delicate connective tissue containing branched cells. There is no reason to suppose that the bone-corpuscles take any active part in the inflammatory processes in bone; all the changes observed proceed from the Haversian canals. The nature of the tissue in which the inflammation is taking place necessarily causes some modifications in the phenomena. Exudation and migration of the corpuscles occur as in other structures, but the amount is somewhat limited by the unyielding nature of the surrounding tissue. The swelling of the delicate connective tissue in the Haversian canals will moreover tend to compress the vessels, and thus in acute inflammation of compact bone death of the affected part is very prone to occur from arrest of the flow of blood through it. Should this not happen, we see the same changes occurring as in other tissues; the new cells increase in number and the original tissue disappears before them. In bone this process is necessarily slow on account of the density of the structure, but ultimately a portion of the solid bone may be as completely destroyed before the advancing cells as are the soft tissues in the formation of an abscess-cavity, or in ulceration of the skin. When recovery takes place the inflammatory products develop into bone instead of into fibrous tissue as in the soft parts. The compact tissue is liable to chronic inflammatory affections of the same type as those leading to fibroid induration of the soft parts, but in bone the product of the process is new osseous tissue which develops in the Haversian canals, gradually narrowing them, and rendering the texture more dense than natural.

The inflammatory processes observed in compact bone are the following:—
1. Rarefying or rarefactive osteitis; (2) Osteoplastic or condensing osteitis; and (3) Necrosis.

Rarefying or Rarefactive Osteitis.—This may occur as a secondary effect of inflammation commencing in the periosteum or in the medulla. It is observed also as the result of injury, as in a piece of bone denuded of its periosteum, or on each side of a fracture. In many cases its original cause is very obscure.

A portion of compact bone undergoing this change is in the earliest stages observed to be slightly redder than natural; the openings of the Haversian canals after a time become somewhat increased in size, and consequently a larger number are visible to the naked eye. As the process advances the

NATURAL HISTORY OF BONE AND ITS EFFECTS.

...at the expense of the solid bone surrounding them, ...a sufficient size they can be seen to contain a small ... granulation-tissue surrounding the vessel. If a portion of ... stage be macerated, it presents a porous spongy appearance, ... cancellous tissue. If the process advance still further, as ... of a piece of dead bone, the neighboring enlarged Haver- ... the solid osseous tissue disappearing entirely, and a soft ... granulation-tissue fills the space once occupied by solid bone. The ... layers of the granulation-tissue may break down into pus under ... conditions that give rise to suppuration elsewhere, or, should the ... case, the new tissue develops into bone by the same process as in ... periostitis, the new osseous tissue being first formed in connection ... the old.

The rarefying osteitis may be limited to a small portion of the bone as in the separation of a sequestrum, or may be diffused over a wide area. In the latter case it is more chronic, and, although rendering the bone more porous than natural, rarely leads to its complete destruction for any great extent.

Microscopic examination of a piece of bone affected by rarefying osteitis shows the following appearances: In the earliest stage the vessels are distended with blood and numerous cells, probably migrated leucocytes, are found in the delicate connective tissue contained in the Haversian canal. In a more advanced stage these cells are greatly increased in number, and the wall of the canal is seen to have been consumed away before them. The destruction of the osseous tissue takes place irregularly in excavated crescentic hollows, first described by Howship, and consequently named '*Howship's lacunae*.' A large number of these will be found to be filled by cells of considerable size containing several nuclei, each cell corresponding to a lacuna. These many-nucleated cells are found wherever bone is being destroyed, whether from inflammation or a physiological process, as the development of the medullary canal, and they are supposed to play some important part in the absorption of the osseous tissue. For this reason they have received the name of *osteoclasts*. They lie directly in contact with the bone, the rest of the space surrounding the vessels being filled with the ordinary small round cells of granulation tissue. Their mode of development and subsequent fate are uncertain. The osseous tissue which is yet undestroyed presents often no evident change. The bone-corpuscles certainly show no signs of taking any part in the process. Should they show any change it is one of degeneration, not of proliferation. They may be unaturally granular, and are sometimes represented merely by an oil-globule, or a mass of fat granules. They can in most cases be seen to be unaltered until the lacunae in which they lie are opened by the advancing absorption of the osseous tissue, and after that their fate is unknown.

When the destructive process has advanced far enough to form a considerable space filled with granulation-cells around the original vessel of the Haversian canal, new capillary loops are found penetrating amongst the new tissue, just as in the development of granulation-tissue in a wound.

The destruction of bone by the pressure of a tumor or an aneurism, or its infiltration by a malignant growth, is carried out by the same process as that just described, but in the former case, when the Haversian canals have become sufficiently enlarged, the special elements of the tumor penetrate into them, displacing the granulation-tissue. The compact tissue may in like manner be invaded by the specific tissue of a syphilitic gumma.

Various terms are applied clinically to this rarefying osteitis under its different modifications. When the process is widely diffused, a large part of the shaft of a bone being rendered more porous than natural without

complete destruction of the bony tissue, it is sometimes termed *inflammatory caries*. When only a localized area is affected, as in the separation of dead from living bone, with complete destruction of the osseous tissue, and subsequent formation of pus from the granulation-tissue replacing it, it is termed *simple ulceration of bone*. When it occurs as the result of the infiltration of the compact tissue by a subperiosteal gumma followed by softening and suppuration of the new growth, it is described as *sypilitic caries*.

Osteoplastic Osteitis or Osteo-sclerosis.—This is always an extremely chronic process. It may occur as a sequence of diffuse rarefactive osteitis, or as the secondary result of some central mischief occurring in the cancellous tissue or medulla, or as a consequence of syphilis. Osteoplastic osteitis is characterized by a development of new bone in the connective tissue surrounding the vessels in the Haversian canals. The mode of formation of the osseous tissue is the same as in osteoplastic periostitis. As the result of the process the bone becomes greatly increased in density, frequently with complete obliteration of many of the Haversian canals. This may even go on to such an extent as to cut off the vascular supply from a portion of bone and thus cause its death. The bone may assume the consistence of ivory. At the same time it may increase in thickness, partly from a simultaneous deposit of bone by the periosteum, and partly apparently from interstitial growth in the bone itself. The new bone, though denser in structure, resembles healthy osseous tissue when examined by the microscope.

The two processes just described, osteoplastic and rarefactive osteitis, not infrequently go on side by side, giving rise to the appearance known as **expansion of bone**. The compact tissue, when thus affected, becomes more spongy than natural, and the arrangement of its structure is often more or less completely altered. In normal compact tissue some of the superficial lamellæ are parallel to the surface, but in the greater part they are arranged circularly around the Haversian canals; not unfrequently, however, we find in chronic osteitis that the compact structure undergoes a peculiar laminated expansion, so that a section of it presents throughout parallel layers concentric with the medulla. The lamellæ are separated from each other by pink vascular tissue. This change is necessarily accompanied by considerable increase in size of the affected bone, which may extend throughout a great part of its length. Microscopic examination shows, in such a case as this, that the pink tissue between the bony laminae is composed chiefly of round cells, like those of ordinary granulation-tissue, but on one side of the lamella the cells in contact with the osseous layer are assuming the form of osteoblasts, indicating that formation of bone is taking place; while, on the other, the surface of the lamella is irregular, presenting the hollows known as Howship's lacunae, and in these are the large, many-nucleated cells, or osteoclasts, which are indicative of destruction of bone. This process, when occurring as a pathological change, is usually regarded as inflammatory, but the close analogy between it and normal growth is evident. In the growing bone of a child the medullary canal is hollowed out by a process similar to that just described, and new bone is constantly deposited on the surface by the periosteum. In chronic osteitis with "expansion" of the bone the chief difference is in the diffusion of the process throughout the compact tissue and its irregularity. If the source of irritation to which the expanding osteitis is due be removed, the destructive part of the change ceases and new bone is formed on both sides of the lamellæ, and thus, while the abnormal size is more or less completely retained, the structure becomes as dense as, or sometimes denser than, normal compact tissue.

In some few cases the appearances presented by the diseased bone are such as to suggest that the periosteum takes but little part in the process, but

more commonly expansion of the compact tissue is associated with laminated deposits of new bone from the periosteum.

Expansion of bone by a tumor is a change of the same character, the destructive processes just described taking place in the parts pressed on by the growth, while at the same time new bone is developed beneath the periosteum. Thus, even when the tumor exceeds the normal bone in size, it is often found still to be surrounded by a shell of osseous tissue.

Syphilitic Osteitis has been already described (vol. i. p. 1070).

Necrosis of the Compact Tissue may be the result of direct injury, as a severe blow. A portion of bone may perish from its vascular supply being cut off by separation of the periosteum by injury or by the formation of pus beneath the membrane; and in like manner suppuration in the medullary canal may cause the death of neighboring compact tissue. When the compact tissue becomes involved in acute inflammation extending to it, either from the medulla or from the periosteum, it is very apt to necrose from pressure upon the vessels in the Haversian canals by the inflammatory exudation within them. Chronic osteoplastic osteitis may also, in some cases, end in necrosis from gradual obliteration of the Haversian canals. It is quite possible that small fragments of bone may die and be subsequently absorbed; but that this may take place it is necessary that the dead portion must be of small size and free from irritating properties. If it have perished in consequence of some infective inflammation, or have been impregnated with decomposing matter, its absorption becomes impossible, for absorption of bone is carried out solely by the medium of the living cells before described, and these cannot exist in a healthy state in the presence of the virus of an infective process or the products of putrefaction. Larger fragments of dead bone are always separated from the living and cast off. This is accomplished entirely at the expense of the living bone. The process by which it is carried out is merely one of rarefying osteitis carried to its highest stage and ending in complete destruction of the osseous tissue where the living is in contact with the dead, its place being occupied by granulation-tissue. The layers of this tissue touching the dead bone break down into pus, and thus complete separation is accomplished. The further details of the process will be given when treating of necrosis clinically.

INFLAMMATORY PROCESSES IN THE MEDULLA OF LONG BONES.—The marrow of a long bone is composed of fat, supported by a delicate connective tissue and traversed by vessels. It contains numerous cells resembling white corpuscles. In contact with the solid bone the connective tissue assumes an imperfect membranous form and is more abundantly vascular, and this layer has received the name of the medullary membrane. It is unnecessary to enter into any great detail in describing the inflammatory processes that occur in the marrow of bone, as they are the same as in other soft structures. The forms of inflammation occurring in the medulla are the following: (1) Simple osteomyelitis; (a) acute, (b) chronic. (2) Diffuse acute osteomyelitis; (a) septic, b infective.

Simple Acute Osteomyelitis is usually of traumatic origin. The phenomena observed are the same as in other soft parts, dilatation of the vessels, exudation and migration of the corpuscles, and gradual disappearance of the normal tissues before the new cells. In compound fractures and amputations it occasionally ends in suppuration, a small collection of pus sometimes forming which discharges itself through the open end of the medullary canal. In simple fractures suppuration never takes place, but the products of the process are developed into bone, thus forming the internal callus (*vide* Repair of Fracture, vol. i. p. 503).

Osteomyelitis in its early stages is recognized by the dark red color of the

marrow. Later on the fat disappears, and soft tissue, having the ordinary pink color of granulation-tissue, takes its place. If bone forms, it appears first in contact with the preexisting osseous tissue.

Chronic osteomyelitis occurs only as a part of more general inflammatory affection of bone. Thus, in an osteoplastic osteitis, we often find the medullary canal encroached on by the newly formed osseous tissue, until in some cases it is completely filled by spongy bone. In necrosis of the compact tissue the neighboring medulla becomes chronically inflamed, and the products of the process undergo ossification.

Acute Diffuse Osteomyelitis is one of the most serious affections of bone. It occurs in two forms, traumatic and idiopathic. The traumatic is usually of septic origin, and is the direct consequence of decomposition of the discharges in a wound communicating with the medullary canal, as in a compound fracture or amputation. The products of putrefaction diffuse themselves in the soft tissue of the medulla and set up acute inflammation, which rapidly ends in suppuration, and often in gangrene of the marrow. There is nothing peculiar about the process beyond the fact that the products, being enclosed by the surrounding solid bone on all sides except at the opening into the canal, tend to diffuse themselves rapidly, often extending to the extremities of the bone at the further end.

Acute diffuse osteomyelitis may result also from the virus of the various infective inflammations which attack wounds, as erysipelas, hospital gangrene, etc., finding admission to the medullary canal. The distinction between these specific inflammations and that arising from the irritation caused by the products of simple putrefaction cannot usually be made, as it may be said that infective traumatic osteomyelitis rarely, if ever, arises when the discharges of the wound are in an aseptic condition.

Idiopathic Infective Osteomyelitis is rarely met with, in this country at any rate, but is described as of frequent occurrence by most German writers; in fact, the cases which most English pathologists describe as acute infective or suppurative periostitis, or as acute necrosis, are by German writers spoken of as acute osteomyelitis. The disease is due to a virus, the nature of which is uncertain, but which is believed to be carried by the blood to the affected bone, and there to excite acute inflammation in much the same way as the virus of scarlet fever causes inflammation of the throat, or that of mumps inflammation of the parotid gland or testicle. The virus increases in quantity in the inflamed area and by diffusing itself in the neighboring parts causes the spread of the inflammation. What it is that determines the particular bone affected when the inflammation commences in the medulla is uncertain, but when the periosteum is primarily affected, and the medulla only implicated by extension through the compact tissue, the origin of the process can often be traced to a blow. Infective osteomyelitis has been experimentally induced by injuring a bone subcutaneously and then injecting putrid fluids containing microscopic organisms into the blood-stream. In the human subject the purulent bones affected in this way has been repeatedly shown to contain microorganisms, but no special form has as yet been found to be invariably associated with the disease.

A bone affected with acute diffuse osteomyelitis of any form presents the following appearance on section. The medulla is in parts redder than

Fig. 496. — Diffuse Osteomyelitis of Humerus after Excision of the Elbow Joint.

natural, and scattered hemorrhages are commonly met with. In other parts it is paler in color and infiltrated with pus, which here and there is collected in abscess-cavities of various size. At each end of the bone the morbid condition extends into the cancellous tissues, the marrow in the spaces presenting the same appearances. If the osteomyelitis is of the traumatic septic form, gray gangrenous patches of marrow are usually present, and the sawn bone is abominably offensive to smell. The compact tissue shows no definite changes, but the periosteum is always swollen and frequently separated from the bone by the formation of pus beneath it.

Acute diffuse osteomyelitis always causes more or less extensive necrosis of the compact tissue, partly depriving it of its vascular supply when supuration takes place, and partly from extension of the diffuse inflammation into the Haversian canals. The veins of the affected bone become inflamed and filled with coagulum. The thrombi being invaded by the infective material, soften and disintegrate, and the fragments bearing with them the infective material are carried into the circulation, and thus embolic pyæmia is a very common result of diffuse osteomyelitis.

INFLAMMATORY AFFECTIONS OF THE CANCELLOUS TISSUE.—The cancelli of the spongy tissue of bone are composed of osseous tissue differing in no respect save that of its arrangement from the compact substance. The spaces are filled with a marrow in most parts identical with that of the medullary canal, but containing less fat. In the vertebrae, ribs, and diploe of the skull, the marrow is red, and contains numerous cells like white corpuscles and others apparently intermediate between white and red. There is no reason to believe that any of the pathological changes observed in cancellous bone begin in the osseous tissue, the starting point of every process, as far as can be ascertained, being the medulla filling the cancellous spaces. The following are the chief inflammatory processes met with in the cancellous tissue: 1. Acute diffuse inflammation; 2. Rarefactive osteitis, (*a*) without supuration, (*b*) with supuration; 3. Osteoplastic osteitis.

Acute Diffuse Inflammation of the Cancellous Tissue is the same process occurring in the medulla of the cancellous tissue as has already been described under the name of acute diffuse osteomyelitis when attacking the marrow of a long bone, and arises under similar conditions, either as the result of the contact of putrid discharges in an open wound, implicating the spongy tissue of a bone, or as an infective process commencing without direct communication with the external air. In many cases it is merely an extension to the ends of the bone from the medullary canal. In it the cancellous spaces become filled with pus, or the medullary tissue may become gangrenous. It always leads to necrosis of the osseous tissue surrounding the spaces.

Rarefying Osteitis is very common in spongy bones, and forms the chief pathological change in a large proportion of the cases clinically spoken of as caries. Rarefying osteitis in cancellous bone is essentially the same process as in the compact tissue. Inflammatory exudation and migration of white corpuscles take place in the medullary tissue, and the original structures disappear before the inflammatory new growth (Fig. 497). The cancelli become gradually thinned, being absorbed in exactly the same way as the lamellæ of the compact tissue. A spiculum of bone removed from the inflamed area shows the same irregular excavations of Howship's lacunæ, in most of which osteoclasts may be seen. The bone-corpuscles have frequently undergone fatty degeneration and sometimes the cells in the lacunæ are represented merely by oil-globules. This is due to interference with the nutrition of the osseous tissue consequent on the changes occurring in the medulla of the cancellous spaces. Finally the bony tissue in the affected area may

entirely disappear, the whole space being occupied by soft vascular granulation-tissue. This may be taken as the type of the process, but numerous modifications occur which require further consideration.

1. The granulation-tissue may grow exuberantly, with rapid destruction

Fig. 488.—Osteitis from a Case of Scrofulous Osteitis of the Bones of the Skull in a Child.

At 4 are seen the so-called Lacunae of Howship: the material filling the dilated cancellous spaces is a more or less cheesy granulation tissue.

2. The bony cancelli, and if reaching a surface, as a cavity of a joint, may form fungating projections. This form is termed *fungating caries* or *caries fungosa*. It is most common in the articular ends of bones.

Fig. 489.—Fungating Process in Head of Tibia.

Fig. 490.—Chronic Rarefactive Osteitis of the Cancellous Tissue with Caseation of the Inflammatory products.

3. After destruction of the bony matter the granulation-tissue may be absorbed and waste away without suppuration. This is most common where

periosteal abscess may be followed by necrosis of a scale of bone, but more commonly after the pus is evacuated it heals without further trouble.

Subacute and Chronic Periostitis may occur as a sequence of the acute form just described; or the disease may from the beginning assume this form when it is due to syphilis, rheumatism, or occurs in a scrofulous subject. Chronic periostitis is always accompanied sooner or later by the formation of new bone (*Osteoplastic Periostitis*, see p. 274). The symptoms consist of a hard, elongated, but somewhat puffy swelling without cutaneous discoloration—a nodule—not distinctly circumscribed, and attended by much pain in the part, especially at night, with tenderness on pressure.

TREATMENT.—In the treatment of the *acute form* of the affection, the free application of leeches, with hot fomentations, will arrest the disease, and give relief to the patient. Should pus form, it must be let out by incision as soon as it is recognized, strict antiseptic precautions being observed in order to diminish the risk of necrosis.

In the more *chronic form*, the continued administration of the iodide of potassium will take down the swelling, remove the nocturnal pains, and materially improve the local condition of the part. In those cases of periostitis which are of syphilitic character, iodide of potassium may be looked upon almost as a specific. Added to this, repeated blistering will be of essential service. If there be much thickening, the parts suffer from the tension of the structures; here considerable relief will be afforded by the free division of the periosteum down to the bone, either through the skin, or subcutaneously by means of a tenotome slid under it.

CHRONIC OSTEITIS AND PERIOSTITIS.

By **Chronic Osteitis and Periostitis** is meant an affection usually attacking long bones, leading to considerable enlargement, with alteration in structure. It is most common in strumous subjects, and seems to arise from slight traumatic causes or exposure to cold. A section of the affected bone shows that the periosteum is thickened and new bone is being formed beneath it (*Osteoplastic Periostitis*, p. 274). The compact tissue has become more porous than natural, and from the simultaneous destruction of the old bone and formation of new, it often shows a peculiar laminated expansion of its structure, so that a section of it presents an appearance of concentric parallel layers (*Rarefying Osteitis and Expansion of Bone*, p. 276). The cancellous tissue may at the same time become denser than natural, and new bone may form, filling the medullary canal (*Osteoplastic Osteitis of the Cancellous Tissue*, p. 283). As the result of these changes in its various component parts, the whole bone may be converted into a uniform mass, with but little distinction between the cancellous and compact tissue. When the process becomes extremely chronic, as it often does, the osteoplastic processes may be more pronounced, and the enlarged bone become extremely dense and ivory-like in structure. Chronic osteitis and periostitis may occur alone, but it is more common to find it associated with necrosis of small portions of the cancellous or central layers of the compact tissue, or with the presence of a chronic abscess in the cancellous tissue. The disease may affect the whole length of a bone (Fig. 502), or may be limited to one end. When it occurs in young subjects it is often accompanied by early union of the epiphyses, which may cause shortening from want of growth. In other cases in which the middle part of the bone is chiefly affected, elongation may take place. I have seen, as the result of chronic osteitis, the tibia from one end a half to two inches longer than its fellow.

SYMPTOMS.—The symptoms of chronic osteitis consist of enlargement of the affected bone, with deeply seated pain in and great tenderness of the part, the pain, as in periostitis, is greatly increased at night, and, when the disease is chronic, is much influenced by the state of the weather. There is no danger connected with this condition; but it often becomes distressing from the severity of the tense and nocturnal pain accompanying it. In strumous subjects there is danger of the process becoming intensified in parts of the bone, and thus leading to necrosis or caries with chronic suppuration.

TREATMENT.—In chronic osteitis and periostitis, when the bone has become thickened and enlarged, but little can be done in the way of cure. The administration of iodide of potassium with the occasional application of leeches will, however, do much to arrest the progress of the disease and relieve pain. Should these means fail in giving relief, and the pain continue of an excessively distressing and persistent character, I have for many years just practised the following operation of *linear osteotomy*. An incision about three inches long is made directly down on the chronically inflamed and indurated bone, being carried through the periosteum, so that the scalpel creates upon the bone. By means of a Hey's saw this cut is extended into the substance of the bone as far as the medullary canal, or deeply into its surrounding tissue. Some bleeding occurs, but it can always be arrested by position and pressure. The wound is then closed. Nothing relieves the tense pain so effectually as this and nothing stops so decidedly the tendency to secondary mischief, whether in the form of caries or of abscess. In this way tension is taken off; and the pain, which appears to be dependent on the compression of inflamed bone by its own condensed structure, is at once relieved. "Linear Osteotomy" is an operation especially applicable to osseous nodes of the long bones, or to chronic osteitis of the articular ends of the tibia, and is a far less severe mode of treatment than trephining the bone, which has occasionally been adopted in such cases; while it is equally efficacious. After a time, when the progress of the disease ceases, the enlarged bone does not give rise to any very serious inconvenience, except such, perhaps as may be occasioned by its bulk.

OSTEITIS DEFORMANS.

In 1876 Sir James Paget read a paper before the Royal Medical and Chirurgical Society of London on five cases of a general disease of the bones, to which he gave the name of *osteitis deformans*. The most marked features of this disease are the following: It begins after middle life, and runs an extremely slow course, lasting even as long as twenty years without affecting the general health to any appreciable degree. "The disease affects most frequently the long bones of the lower extremities and the skull, and is usually symmetrical. The bones enlarge and soften, and those bearing weight yield and become unnaturally curved. The spine may sink and seem converted with greatly increased dorsal and lumbar curves; the pelvis may become wide; the necks of the femora may become nearly horizontal, but the limbs, however misshapen, remain strong, and fit to support the trunk." The skull may become enormously thickened, yet this never gives rise to any signs of pressure on the brain. The disease is accompanied by obscure pains, not especially nocturnal. It has no connection with syphilis, gout, or rheumatism. In three out of the five cases recorded, sarcomata of bone appeared late in life. The bones examined after death show changes extensive of an inflammatory character. The skull is uniformly thickened, but in the long bones the compact tissue is chiefly affected. The thin layer

periosteal abscess may be followed by necrosis of a scale of bone, but more commonly after the pus is evacuated it heals without further trouble.

Subacute and Chronic Periostitis may occur as a sequen^c of the acute form just described; or the disease may from the beginning assume this form when it is due to syphilis, rheumatism, or occurs in a scrofulous subject. *Chronic periostitis* is always accompanied sooner or later by the formation of new bone (*Osteoplastic Periostitis*, see p. 274). The symptoms consist of a hard elongated, but somewhat puffy swelling without cutaneous discoloration—a *nodule*—not distinctly circumscribed, and attended by much pain in the part, especially at night, with tenderness on pressure.

TREATMENT.—In the treatment of the *acute form* of the affection, the free application of leeches, with hot fomentations, will arrest the disease, and give relief to the patient. Should pus form, it must be let out by incision as soon as it is recognized, strict antiseptic precautions being observed in order to diminish the risk of necrosis.

In the more *chronic form*, the continued administration of the iodide of potassium will take down the swelling, remove the nocturnal pains, and materially improve the local condition of the part. In these cases of periostitis which are of syphilitic character, iodide of potassium may be looked upon almost as a specific. Added to this, repeated blistering will be of essential service. If there be much thickening, the parts suffer from the tension of the structures: here considerable relief will be afforded by the free division of the periosteum down to the bone, either through the skin, or subcutaneously by means of a tenotome slid under it.

CHRONIC OSTEITIS AND PERIOSTITIS.

By **Chronic Osteitis and Periostitis** is meant an affection usually attacking long bones, leading to considerable enlargement, with alteration in structure. It is most common in strumous subjects, and seems to arise from slight traumatic causes or exposure to cold. A section of the affected bone shows that the periosteum is thickened and new bone is being formed beneath it (*Osteoplastic Periostitis*, p. 274). The compact tissue has become more porous than natural, and from the simultaneous destruction of the old bone and formation of new, it often shows a peculiar laminated expansion of its structure, so that a section of it presents an appearance of concentric parallel layers (*Rarefying Osteitis and Expansion of Bone*, p. 276). The cancellous tissue may at the same time become denser than natural, and new bone may form, filling the medullary canal (*Osteoplastic Osteitis of the Cancellous Tissue*, p. 283). As the result of these changes in its various component parts the whole bone may be converted into a uniform mass, with but little distinction between the cancellous and compact tissue. When the process becomes extremely chronic, as it often does, the osteoplastic processes may be more pronounced, and the enlarged bone become extremely dense and ivory-like in structure. Chronic osteitis and periostitis may occur alone, but it is more common to find it associated with necrosis of small portions of the cancellous or central layers of the compact tissue, or with the presence of a chronic abscess in the cancellous tissue. The disease may affect the whole length of a bone (Fig. 502), or may be limited to one end. When it occurs in young subjects it is often accompanied by early union of the epiphyses, which may cause shortening from want of growth. In other cases in which the middle part of the bone is chiefly affected, elongation may take place. I have seen, as the result of chronic osteitis, the tibia from one end a half to two inches longer than its fellow.

SYMPTOMS.—The symptoms of chronic osteitis consist of enlargement of the affected bone, with deeply seated pain in and great tenderness of the bone, the pain, as in pericarditis, is greatly increased at night, and, when the disease is chronic, is much influenced by the state of the weather. There is no danger connected with this condition; but it often becomes distressing from the severity of the tensive and nocturnal pain accompanying it. In arthritic subjects there is danger of the process becoming intensified in parts of the bone, and thus leading to necrosis or caries with chronic suppuration.

TREATMENT.—In chronic osteitis and periostitis, when the bone has become thickened and enlarged, but little can be done in the way of cure. The administration of iodide of potassium with the occasional application of blisters will, however, do much to arrest the progress of the disease and relieve pain. Should these means fail in giving relief, and the pain continue of an excessively distressing and persistent character, I have for many years past practised the following operation of *linear osteotomy*. An incision about three inches long is made directly down on the chronically inflamed and thickened bone, being carried through the periosteum, so that the scalpel passes upon the bone. By means of a Hey's saw this cut is extended into the substance of the bone as far as the medullary canal, or deeply into its cancellous tissue. Some bleeding occurs, but it can always be arrested by position and pressure. The wound is then closed. Nothing relieves the tensive pain so effectually as this and nothing stops so decidedly the tendency to secondary mischief, whether in the form of caries or of abscess. In this way tension is taken off; and the pain, which appears to be dependent on the compression of inflamed bone by its own condensed structure, is at once relieved. "Linear Osteotomy" is an operation especially applicable to cancerous nodes of the long bones, or to chronic osteitis of the articular ends of the tibia, and is a far less severe mode of treatment than trephining the bone, which has occasionally been adopted in such cases; while it is equally efficacious. After a time, when the progress of the disease ceases, the enlarged bone does not give rise to any very serious inconvenience, except such, perhaps, as may be occasioned by its bulk.

OSTEITIS DEFORMANS.

In 1876, Sir James Paget read a paper before the Royal Medical and Chirurgical Society of London on five cases of a general disease of the bones, to which he gave the name of *osteitis deformans*. The most marked features of the disease are the following: It begins after middle life, and runs an extremely slow course, lasting even as long as twenty years without affecting the general health to any appreciable degree. "The disease affects most frequently the long bones of the lower extremities and the skull, and is usually symmetrical. The bones enlarge and soften, and those bearing weight yield and become unnaturally curved. The spine may sink and seem characterised with greatly increased dorsal and lumbar curves; the pelvis may become wide; the necks of the femora may become nearly horizontal, but the limbs, however misshapen, remain strong, and fit to support the trunk." The skull may become enormously thickened, yet this never gives rise to any signs of pressure on the brain. The disease is accompanied by obscure pains, not especially nocturnal. It has no connection with syphilis, gout, or rheumatism. In three out of the five cases recorded, sarcomata of bone appeared late in life. The bones examined after death show changes evidently of an inflammatory character. The skull is uniformly thickened, but in the long bones the compact tissue is chiefly affected. The thin layer

of compact bone on the articular surface is thickened and encroaches on the cancellous tissue. The thickened bone is soft and spongy, its substance is very vascular, and its surface is grooved with lines for the vessels of the periosteum. Neither the periosteum nor the medulla present any marked change.

Microscopic examination of one of Sir James Paget's cases by H. T. Butler confirmed the opinion that the disease is inflammatory. He says: "The whole microscopic architecture of the bone had been altered; the structure appeared to have been almost entirely removed and laid down afresh on a different plan and in a larger mould." The enlarged Haversian canals contained a tissue closely resembling that found in ordinary rarefying osteitis, but more fibrillar, and containing fewer cells. In some of the canals the process of destruction was evidently progressing. Howship's lacunae with osteoclasts (p. 276) being seen, while in other parts new bone was being formed as was shown by the presence of osteoblasts. Beyond this there is no evidence to show the exact nature or causes of this disease. No treatment seems to be of any use.

CHRONIC ABSCESS OF BONE.

Chronic abscesses in bone are usually met with in the cancellous tissue and occur with special frequency in the head and lower end of the tibia. The abscess forms as the result of rarefying osteitis of a localized portion of the cancellous tissue (p. 275). This process continues till the bony canals are completely destroyed. Subsequently the inflammatory products undergo fatty degeneration and soften, forming thick curdy fluid containing few recognizable pus-cells and large quantities of fatty debris. The process may continue gradually to extend, and may thus undermine the contiguous cartilage, and eventually the abscess may burst into the neighboring joint (Fig. 500). The tendency for the pus to burrow in this direction is increased by

Fig. 500.—Abscess in the Head of the Tibia.

the want of formation of any new bone beneath the cartilage, while it readily takes place under the periosteum. In young subjects, before the union of the epiphyses, the pus commonly finds its way to the surface through the soft tissue between the epiphyses and the diaphysis. Very frequently, however, the disease becomes excessively chronic. The abscess is then of small size and deeply seated in the cancellous tissue. The inflammation in the bone immediately surrounding the cavity in these cases often assumes the osteoplastic form, and the collection of pus becomes surrounded by a wall of excessively dense hard bone, and in this state it may remain unchanged for many months or even years. The irritation caused by the presence of the pus usually gives rise to chronic inflammatory changes in the neighboring compact tissue and periosteum. These assume the form described in the previous page as "chronic osteitis and periostitis," and produce considerable general enlargement of the affected end of the bone. Chronic abscesses have been occasionally, but more rarely, met with in the medullary canal.

The quantity of pus contained in a chronic abscess of bone is usually very small, amounting to one or two drachms, but Stanley has recorded cases in which an ounce or more was found.

It may happen that degeneration of the inflammatory products or suppuration may take place before the rarefying process has advanced far enough to cause complete destruction of the cancellous tissue. The undestroyed bone then perishes, becomes separated from the surrounding parts, and lies loose in the cavity of the abscess.

In some cases abscess of bone is associated with chronic osteitis of a considerable portion or the whole of the shaft, the bone becoming greatly enlarged, thickened, and generally diseased from end to end. Fig. 502 is a representation of a section of the tibia in such a state of combined suppuration and inflammatory hypertrophy, removed by amputation from a woman who had suffered for 23 years from the disease. In such cases, amputation or excision is the sure means of relief.

The *Causes of Chronic Abscess of Bone* are often somewhat doubtful. It occurs almost exclusively in scrofulous subjects, and there can be no doubt that the immediate cause in a large proportion of cases is the deposit of tubercle in the medulla of the cancellous tissue. This sets up inflammation around it and finally softens in the same way as in other parts. In some cases the disease arises apparently from injury.

The *Symptoms of chronic abscess of bone* are usually of the following character. The patient, after the receipt of an injury, perhaps, has noticed that at one spot the affected bone has become swollen and painful; the skin covering it preserves its natural color in the majority of cases, but in some instances becomes red, gazed, and edematous; the pain, which is of a lancinating and burning character, is usually remittent, often ceasing for days, weeks, or months, and then returning, under the influence of very trivial causes, with its original severity. It is especially troublesome at night, and is always associated with a degree of tenderness of the part; and indeed, in the intervals of its recession, it will be found on careful examination that there is always one tender spot in the enlarged and indurated bone. The long persistence, for years perhaps, of these signs will usually point to the existence of a small circumscribed abscess under the thickened wall of the bone. It must be borne in mind, however, that the same local symptoms may be caused by four conditions: 1. By a chronic abscess without necrosis. 2. By the inclusion of a small piece of dead bone surrounded by pus within a dense and impervious casing. 3. By simple chronic osteitis and periostitis (p. 284), without suppuration or necrosis; and, 4. By the growth of a cystic or other tumor within the bone. For all practical purposes the diagnosis is of little consequence, as the operative treatment is the same, whether the symptoms arise from the confinement of a few drops of pus or from the inclusion of necrosed bone, and the diagnosis of the presence of a tumor can often be made only by a similar operation.

The danger of chronic abscess of the end of a long bone will greatly depend on its proximity to the articular surface. If near this, it will probably lead to perforation of the cartilage, so that the pus enters the joint, which then becomes acutely inflamed and often destroyed.

If the chronic abscess be situated in the diaphysis near the junction of the epiphysis with the shaft, this event is not so likely to occur. The surrounding bone simply becomes thickened; and though the health may suffer from the constant wearing pain, the joint is not in peril, and relief may readily be given by operation.

Treatment.—As a circumscribed abscess in bone cannot perforate the dense osseous structure overlying it by any process analogous to the pointing and discharge of an abscess in the soft parts, it becomes necessary for the surgeon to open up a vent for the pus. This may be done either by linear osteotomy or by the trephine. In some cases simple linear osteotomy, as described at

p. 285, may be practised; but should the bone be much thickened and the osseous structures greatly indurated, the trephine is the best instrument to use for opening the abscess. The proper way of doing this has been pointed out by Quesnay and Brudie. It consists in trephining the bone, so as to

make an aperture for the exit of the pus. So soon as a vent has been given to the pus, which is usually cheesy, the patient will experience great and permanent relief. In performing this operation, there are several points that deserve special attention. The limb having been made bloodless by Eschmarch's method, the bone must be exposed by a T- or V-shaped incision, made over the spot which has been found to be uniformly tender on pressure; and to this the trephine should be applied. The trephine should have a small and deep crown of the size and shape represented in Fig. 501; and it is well always to be provided with two instruments of the same shape and size that will exactly fit the same hole, lest one become disabled by the density and hardness of the osseous case, as I have seen happen. When the trephine has penetrated to a sufficient depth, the button of bone may be removed by means of an elevator; but care should be taken not to perforate the whole thickness of the bone. The diseased cavity will very commonly at once be opened in this way, a small quantity of pus escaping, which may, if the limb be not bloodless, be readily overlooked, as it is carried away in streaks with the blood, which flows freely from the cut bone. Should no pus escape, perhaps a portion of dead bone may be exposed; if so, it must be removed with a gouge. But if neither of these conditions be found, the surgeon must not be disappointed, but pierce the neighboring osseous tissue in different directions by means of a perforator, when perhaps the abscess will be opened; should it not be so, the patient will still in all probability be materially benefited by the consequent relief to the compression

Fig. 501. Bone Trephine.

Fig. 502. — Section of Tibia, showing Chronic Osteitis and Circumscribed Abscesses of many years' duration.

removal of the circle of bone, and of the osseous tissue.

The operation should, if possible, be performed with antiseptic precautions. The cavity should be thoroughly cleaned with a small piece of sponge soaked in some antiseptic solution (as chloride of zinc, gr. xx to $\frac{1}{2}$), in order to remove any fragments of necrosed bone or sawdust. It may then be dressed with an efficient antiseptic dressing. Among the best are carbolic gauze, and absorbent iodoform or salicylic wool. The dry wool dressings may be left unchanged, if all goes on well, for a week or even a month if no discharge soaks through. If decomposition can be prevented, the cavity often becomes

filled with a blood-clot into which the granulation-tissue rapidly sprouts from the surrounding bone until in two or three weeks it may be completely closed. If the cavity becomes filled with septic discharges, the process of healing is much delayed. Subsequently the granulation-tissue develops into bone and the limb recovers its former strength and utility.

DIFFUSE SEPTIC OSTEOMYELITIS.

Diffuse acute inflammation, ending in suppuration of the medullary tissue of a bone, may arise as a consequence of open injuries, such as compound fractures or amputations, or occur as an acute disease arising without evident cause. I shall here deal only with the former condition, the latter being most conveniently considered when discussing the disease commonly known in this country as "acute necrosis."

Acute septic osteomyelitis was formerly a common consequence of injuries by which the medullary canal was opened, such as compound fractures or amputations, and it was also often met with when the cancellous tissue only was implicated, as in extension of the knee. Compound fissured fractures of the long bones, such as result from gunshot wounds, are specially prone to be followed by it. The condition is essentially connected with decomposition of the discharges of the wound through which the bone has been exposed, and more especially with the presence of septic matter pent up in contact with the open medullary canal or cancellous tissue. The improved treatment of wounds and the use of antiseptics has now almost abolished the disease in civil though it still retains its hold in military practice.

In certain very rare cases diffuse osteomyelitis has been met with as the result of subcutaneous injuries. In the majority of these cases it formed a secondary effect of general blood-poisoning from a foul wound on some other part of the body. That this is the most probable explanation of these cases is shown by the fact that simple fractures can be made to suppurate in animals, and osteomyelitis can often be induced in the injured bone by injecting septic matter into the blood stream.

The pathology of the process is not difficult to understand. If septic matter be put up in the deep parts of a wound in contact with the opened cancellous tissue or the medullary canal, the products of decomposition will readily diffuse themselves into the soft medullary tissue. This becomes acutely inflamed, and pus is rapidly formed, or, owing to the confined space in which the medullary tissue is contained, the inflammatory swelling may arrest the circulation and cause gangrene. Whether it ends in gangrene or suppuration the products of the inflammation in their turn decompose, and thus the process rapidly spreads throughout the medullary tissue. Simple decomposition is thus sufficient, in most cases, to explain the phenomena of diffuse osteomyelitis, without supposing that any specific virus is present. It is probable, however, that in many cases the wound is really infected with some specific virus analogous to that of diffuse phlegmonous erysipelas or spreading gangrene, for diffuse osteomyelitis may attack several patients in one ward at the same time, and, in fact, is predisposed to by all these conditions which have already been described as influencing the occurrence of other infective processes in wounds. The pus and gangrenous medulla are always found to contain microscopic organisms, but they are not uniform in character. The process is often accompanied by offensive decomposition and the breaking of the gangrenous tissues from the generation of sulphuretted hydrogen. Septic osteomyelitis is one of the most common causes of embolic pyæmia. The connection between these conditions has been specially pointed out by Sir Joseph Fayrer, who has had abundant opportunities of studying

the disease in India. The frequency with which pyæmia follows this affection is due to the fact that the veins of bone, lying as they do in rigid canals, do not readily collapse, a condition highly favorable to the extension of thrombosis. The thrombi thus formed become impregnated with the products of the unhealthy process, disintegrate, and are washed on into the blood-stream, causing centres of suppuration wherever they lodge. It is this that makes septic osteomyelitis a most dangerous disease, frequently proving fatal. There is, in fact, a triple pathological sequence of osteomyelitis, osteophlebitis, and pyæmia, which is of a marked character.

Fat-embolism has been observed in many cases of acute osteomyelitis, the liquid fat from the broken-down marrow being forced into the vessels or lymphatics by the pressure of the inflammatory exudation. If the emboli are impregnated with the products of decomposition, they may give rise to abscesses in distant parts where they lodge.

If the patient escape the dangers of pyæmia, the disease almost invariably leads to more or less extensive necrosis affecting chiefly the inner layer of the compact tissue. The long sequestra so frequently removed from stumps, especially after amputation of the thigh, are the result of this process (see vol. i. p. 99).

After death, the appearances presented by the inflamed bone will, if it have been the seat of compound fracture, be usually most marked in the upper fragment; if it have been the seat of amputation or excision, they will extend through the whole of the bone that is left. They are as follows. The periosteum and outer surface of the bone will appear to be slightly injected. On making a longitudinal section of the bone, the part that is inflamed will be found to present the following appearances. The medullary canal is filled with pus or a reddish puriform fluid, often abominably offensive; the medulla is swollen, soft, pulpy, of a deep red or reddish-brown color; the compact bone has a pinkish tinge, and the cancellous osseous structure is often of a bright rosy hue. In a case of compound fracture, the contrast between the deep coloration of the inflamed portion of bone and the naturally pallid appearance presented by that which is not diseased, and more particularly the deep red hue of the medulla in the one, and the pale yellowish waxy-looking fat filling the medullary canal in the other, is most striking and remarkable. Fayrer describes the medullary canal, in advanced stages of the disease, as being filled with a mass of dead blackened medulla, debris of bone, and pus.

SYMPTOMS.—In acute osteomyelitis, after an injury to or an operation involving the bone, the limb swells, with deep-seated severe aching pain and much tenderness. Abscesses form often unconnected with the original wound, and profuse suppuration is established. The suppuration may amount to many ounces of pus in the day, and the discharge is often dark-colored and fetid. The soft parts retract from the bone, and this where exposed is dry, yellow, and dead, being denuded of periosteum. Septic inflammation and suppuration of the diploe are not uncommon in head injuries. In such cases the scalp is swollen, the periosteum loosened from the bone, and the outer table dry and bare. If the outer table be cut away after death, the red diploe will be found infiltrated by offensive pus.

The constitutional symptoms are those of severe septic fever. The temperature is seldom below 103° F. In many cases the symptoms soon become those of acute pyæmia. If the patient escapes pyæmia the fever subsides, and subsequent symptoms are merely those dependent upon the presence of the necrosed bone.

TREATMENT consists in supporting the patient's constitutional powers by a tonic and stimulating regimen, and by scrupulous attention to hygienic rules.

The less acute forms of the disease call for no treatment beyond attention to cleanliness while the sequestra are becoming loose enough for removal.

In the more acute forms which threaten to terminate in pyæmia, nothing can be done so far as the affected bone is concerned, except its removal; but whether this should be done in the continuity of the bone or at a higher joint, is a question on which different opinions are entertained among surgical authorities. If an operation be performed upon the continuity of a bone affected with diffuse suppuration in the medullary canal, the septic inflammation will most likely recur in the part of the bone which is left. Hence, if secondary amputation of an injured limb should be rendered necessary, the bone being affected with osteomyelitis, it is strongly urged, by some Surgeons, especially by J. Roux, that the operation should be performed at some point above the injured and diseased bone, in preference to amputation through its continuity. Roux, who had extensive experience in the Italian war of 1859, successfully disarticulated the thigh at the hip-joint, in four cases of osteomyelitis consequent on gunshot injuries of the lower end of the femur. Of 22 cases in which he performed secondary disarticulation of other joints for osteomyelitis, all recovered; whereas every soldier died, whose limb was secondarily amputated through the continuity of the injured bone after the battles of Magenta, Montebello, Marignano, and Solferino. On the other hand, Larrey did not consider disarticulation absolutely indispensable, even in cases of acute osteomyelitis; and Longmore has met with cases in which recovery has followed the simple removal of portions of dead bone—the disease in these instances having assumed a chronic form. Fayrer advises that, where osteomyelitis is suspected to be present in a stump after amputation, the medulla should be examined by a probe. If this soon impinge on healthy bleeding medulla, the Surgeon may wait for the efforts of nature to throw off the diseased bone; if, on the other hand, the probe encounter only dead bone and pus, then the sooner amputation is performed, the better.

The special danger in osteomyelitis consists in the tendency to the superincumbence of osteophlebitis and pyæmia; and, in deciding upon the amputation or exarticulation of a bone thus affected, it is of the first importance not to delay the operation until pyæmic symptoms have set in. There is a period between the development of the local inflammation and the constitutional pyæmia, which it is most important not to allow to slip by. During this period the patient is affected by surgical fever, but there are no rigors. It is once the characteristic rigors and the high temperature and profuse sweats of pyæmia have set in, I believe that operation can be of no use, as the patient will certainly perish from secondary deposits or general blood-poisoning. But, before rigors have occurred, the amputation may be done with a good prospect of success. The unsuccessful results of the treatment of this disease renders it all the more imperatively necessary to prevent it by the adoption of efficient antiseptic dressing and proper attention to the hygienic surroundings of the patient. But in military practice this is not always possible.

It has been suggested, instead of amputating at once, to scoop out the medulla with a sharp spoon and to introduce iodoform into the canal. Perthez has recently recorded 8 cases in which he carried out this treatment when the symptoms of osteomyelitis had set in after amputations. In three the whole of the medullary canal remaining was scraped out, and in the other five a length of from 1½ to 3 inches was treated in this way; all recovered without pyæmia. The treatment certainly deserves a trial when amputation is for any reason unadvisable.

ACUTE NECROSIS.

Acute Necrosis is an acute infective inflammation almost exclusively met with before the growth of the skeleton has completely ceased. The affection is known by many other names, such as acute diffuse periostitis, infective periostitis, infective periostitis and osteomyelitis, acute infective osteomyelitis, acute suppurative epiphysitis, necrosal fever and bone-typhus; but the term "acute necrosis" is perhaps the best in the present state of our knowledge, as it does not imply any theory as to the exact nature of the disease and the starting point of the inflammation.

SYMPTOMS. A typical case of acute necrosis presents the following symptoms. The patient is usually a child below the age of puberty, and most commonly a male. He is often strumous and usually in somewhat feeble health, possibly the result of a recent attack of some acute specific disease, as scarlet fever or measles. There is in most cases a history of some slight injury, but this is by no means constant. The attack begins with a sudden invasion like that of a specific fever. There is high temperature, often reaching 105° F. or even higher, occasionally with a rigor. Headache, loss of appetite, thirst, and sometimes vomiting or diarrhoea are present. At first the local affection may escape observation, and such cases are not unfrequently mistaken at the commencement for one of the acute specific diseases. By the second or third day, however, the local symptoms become manifest. The parts covering one of the long bones, most commonly the tibia, femur, or humerus, are found to be swollen and acutely tender. At first the skin is pale, but it soon becomes reddened. By the fourth or fifth day, or sometimes not till the end of a week, distinct fluctuation is recognized, often extending over the whole of the shaft of the affected bone. At this time on moving the limb, distinct, though somewhat soft crepitus may be felt, and it will then be found that one, or sometimes both the epiphyses may be loosened from the diaphysis. As a rule the joints escape, but occasionally one or both of the articulations into which the bone enters become distended with fluid. If at this stage an incision be made into the swollen parts down to the bone, a large quantity of pus escapes, and on inserting the finger the greater part of the diaphysis may be felt to be denuded of its periosteum. All this time the febrile disturbance persists, and by the end of a week may assume the ordinary characters of pyæmia. Symptoms of pneumonia, pleurisy, and pericarditis may supervene and death take place before the abscess has been opened. The disease does not, however, always run this typical course. The following are the chief modifications met with. The threatened suppuration in some very rare cases does not take place. The inflammation of the periosteum gradually subsides in intensity, and assumes the osteoplastic form. A case of this kind occurred lately in University College Hospital in a youth aged about 19. No suppuration took place, the acute symptoms rapidly subsided, and the femur became gradually enlarged to more than double its natural size throughout the whole shaft, from formation of new bone under the periosteum. In other cases, although pus forms early, the extent to which the periosteum is raised from the bone is more limited, being confined to one end or the middle of the shaft. In these cases the course of the disease is usually less acute, and the abscess may become localized and gradually point towards the surface. Separation of the epiphyses is by no means a constant occurrence, the younger the patient the more likely it is to occur. Battey states that a disease of exactly the same character may occur in adults, but this is somewhat doubtful.

Pathology.—Much difference of opinion still exists as to the exact nature of this disease and its point of origin. Holmes, and with him most English surgeons, regard it as an acute diffuse inflammation commencing in the periosteum. Dent and others have published cases proving that at any rate it often arises in this way. In Germany and France it is more commonly described as acute osteomyelitis, and is believed to commence in the medulla. There is no doubt that in fatal cases it is very common to find the medulla inflamed and often suppurating, but this is by no means constant, and in many cases at least is evidently secondary. In a case which lately occurred at University College Hospital, a section of the bone showed the medulla to be inflamed on one side only, in contact with the part of the compact tissue which was denuded of its periosteum, the remainder of the marrow being perfectly healthy. The inflammation was evidently of a more recent date than that of the periosteum. Others have supposed that the compact tissue is primarily affected, but of this there is no evidence. That the inflammation is infective in character is shown by its tendency to spread, and by the frequency with which it is followed by pyæmia, even before the abscess has been opened. Microorganisms have been repeatedly demonstrated in the pus when first evacuated, but no specific form has yet been proved to be invariably associated with the disease. The hypothesis suggested as an explanation of the affection is that it is due to a specific virus entering the blood from without, and finding the nidus for its development in the vascular growing tissue beneath the periosteum, or in the layer of cartilage between the shaft and the epiphyses, the determining cause of the local outbreak being, in most cases, some slight injury with extravasation of blood. The pus, when first let out, is always free from any unpleasant odor. The rapid extension of the suppuration is partly due to the infective nature of the pus and partly to the fact that it is pent-up beneath the dense fibrous layer of the periosteum.

Results.—As the name "acute necrosis" implies, the disease almost invariably results in more or less extensive death of the compact tissue. The extent of the necrosis by no means necessarily corresponds to the area from which the periosteum has been raised by the pus, for, after this has been evacuated, the membrane may adhere again to a considerable extent, and the connection between its vessels and those of the bone be reestablished. In a case lately in University College Hospital, the tibia was felt to be bare from one end of the shaft to the other, yet after free incisions were made no necrosis followed, except over an area of about one square inch near the lower end. The after-history of the dead bone, the process of separation of the sequestrum and repair, will be fully described with necrosis in general.

Diagnosis.—Before the local symptoms become evident, especially in fat children, the disease is easily mistaken for one of the acute specific fevers. So likely is this to happen, that in cases of sudden severe febrile disturbance of doubtful nature in children, the bones should always be examined. When the swelling sets in, it may be mistaken for phlegmonous erysipelas or cellulitis, but these conditions are rare in childhood. When pus is suspected, a puncture should be made with a grooved needle or an aspirator, by which the diagnosis can usually be cleared up.

Prognosis.—The prognosis of acute necrosis is always grave, but, as Billroth points out, it is probably not so fatal as hospital statistics would make it appear. The milder cases, in which the extension of the inflammation is limited, are often treated at home, and come under hospital treatment only at a later period, for the removal of the sequestra. In fact, the great majority of cases of extensive necrosis of the long bones in young subjects are the result of this disease.

Treatment.—The only treatment is to cut down upon the bone and let out the pus from beneath the periosteum at the earliest possible period. In the thigh the incision is best made on the outer side, in the leg in front, over the tibia. The incisions must be free, and, if necessary, several may be made. The wounds must be well drained and treated antiseptically. If the discharge be allowed to decompose, the danger of the patient will be greatly increased. The result of the treatment is usually immediately to relieve the constitutional symptoms and arrest the progress of the disease, but in a certain proportion of cases general infection may have taken place before the abscess was recognized, and the result is then always fatal.

If after the incisions have been made the discharge remains very profuse and threatens to exhaust the patient, amputation may sometimes be necessary. If the shaft of the bone is separated at each end from the epiphyses and lies loose in the cavity of the abscess, it becomes a question whether it should be removed at once or left, in the hope that it may partly recover or may at least serve as a support during the formation of the new bone from the periosteum. Numerous cases have been recorded by Holmes, J. Bell, Macnamara, and others, in which early removal has been practiced with excellent results. New bone is slowly formed from the periosteum, and after a few months the limb is in most cases almost as strong as before the operation. The removal of the bone can usually be accomplished by simply exposing it by a free incision, laying hold of it with the lion forceps and twisting it out. In some cases the operation is facilitated by dividing the shaft into two pieces with a chain-saw. If the bone on examination be found to be firmly attached, it should be left alone. It is only in those cases in which there is reason to believe that the whole diaphysis is separated from the periosteum and the epiphyses that the operation is justifiable.

CARIES.

The term **Caries** has been used with considerable laxity, so that it cannot be said to have any definite pathological meaning. It is, in fact, applied to every slowly progressive ulceration of bone except that concerned in the separation of a sequestrum from the surrounding living bone. All these processes belong to the class of rarefying inflammations of bone, that is to say, the bony tissue is gradually absorbed before an advancing inflammatory new growth proceeding from the vascular tissue, either in the medulla of cancellous bone, or in the Haversian canals of compact bone. These processes have already been described (pp. 275, 280).

The modifications of caries depend upon the cause of the disease, the part of the bone affected, and the stage of the process in which suppuration, or degeneration of the inflammatory products takes place.

The **Causes** of caries are very various. As in all other inflammatory processes we have to consider, first, the constitutional or local condition which predisposes the tissue to inflammation; and, secondly, the source of irritation which is the immediate cause of the process. Caries occurs most frequently in strumous subjects, in whom, as before stated (see *Scrofula*, vol. i. p. 1014), inflammation is prone to be set up by slight causes, and to persist. The immediate cause of the disease is, in many cases, an injury. This is very frequently the case when it starts in the soft tissue, between the epiphysis and diaphysis of a growing bone, or in the bodies of the vertebra. The persistence of the process in these cases is due chiefly to want of rest, the diseased bone being constantly exposed to slight mechanical injury whenever the part is moved or the weight of the body is thrown upon it. That this is the true explanation of many cases is shown by the readiness with which cure takes

place when the diseased part is put at perfect rest. This is also well illustrated in some cases of disease of the hip-joint, with caries of the acetabulum. If excision takes place, the carious cavity, being relieved from the friction at the head of the bone, frequently heals rapidly. If the cause of the continuance of the inflammation be not removed, suppuration frequently takes place.

Another very common cause of caries is the deposit of tubercle in the cancellous tissue of bones. Tubercle undergoes the same changes in bone as elsewhere; it caseates early and subsequently softens, exciting inflammation in the parts around it. The observations of all pathologists during the last few years have tended to prove that the great majority of all cases of caries affecting the short bones of the tarsus and the cancellous tissue of the heads at the long bones are dependent on the presence of tubercle.

The fact that Billroth has found cheesy tubercular deposits in internal organs in 54 per cent. of the cases of caries examined by him is a strong confirmation of this view. He gives the proportions in which these were met with in disease of the different bones as follows: shoulder-joint, 77.7 per cent.; bones of the chest, 65.5; ankle, 64; knee, 62.6; elbow, 62.3; spine, 56.8; wrist, 51.2; pelvis, 50.5; hip, 47.5; tibia, 58; skull and face, 33.6. The large were most commonly affected. It is probable that in many of these the general infection was secondary to the disease of the bone, though it is quite possible that in some the reverse may have been the case. In some cases it is possible that an injury may serve as the starting point of the disease, the tubercle being deposited as a secondary complication.

Syphilitic caries has already been described (see Syphilis, vol. i. p. 1071). It affects most commonly the surface of bones and is then the result of a softening subperiosteal gumma. The disease does not penetrate deeply, but leaves the surface rough and porous, and is accompanied by a good deal of inflammation of the soft parts around the affected bone. It occurs most frequently in adults and is very chronic.

In all forms of caries in which suppuration takes place as soon as the resulting abscess is opened, decomposition of the discharges ensues, unless precautions be taken to prevent it, and the irritation caused by the contact of the septic matter with the diseased surface tends to perpetuate the chronic inflammation and cause extension of the destruction of the bone.

In wounds of joints caries may result after destruction of the cartilages caused from the combined irritation of the friction or pressure of the articular surfaces against each other and the contact of septic matter.

Caries may, therefore, be divided, according to its cause, into simple, tubercular and syphilitic. All these forms are predisposed to by a scrofulous constitution and aggravated by decomposition of the discharges when this happens. It is not always possible to distinguish clinically between the different varieties.

Caries is divided also into *superficial*, *central*, or *articular* according to the part of the bone which it affects.

Many other terms are applied to caries, according to the various modifications which the process may undergo.

When the inflammatory new growth forms rapidly in the cancellous spaces such that soon become filled with vascular granulation-tissue before which the bony canals waste away and finally disappear, the disease is termed *fungating caries* or *caries fungosa*. This form is common in the short bones and in the epiphyses of long bones. If the morbid process reaches the cavity as a part of the fungating granulation-tissue sprouts into it, and spreads over the cartilages and synovial membrane, leading finally to complete destruction of the articulation (see Diseases of Joints). After reaching a certain degree

of development, fatty degeneration sets in in the new tissue, and this is usually followed by softening and slow suppuration. Fungating caries is most commonly associated with the presence of tubercle, but it is not yet proved that it is always so, or that when tubercles, with the characteristic bacilli, are found in the fungating tissue, they have been the primary cause of the process. When the bone is extensively destroyed, as is frequently seen in the vertebrae, without the formation of pus, the disease is termed *dry caries* or *caries sicca*. In dry caries the granulation-tissue may be partly absorbed and partly developed into new bone, if recovery takes place without the formation of pus at any stage of the disease. Thus, in many cases of recovery from caries of the spine we find the whole body of a vertebra has disappeared, those above and below it having come in contact with each other and become firmly united by new bone (see *Caries of the Spine*). When suppuration takes place the process is usually slow, the result being the formation of a chronic abscess with thick, curdy pus, which gradually advances towards the surface. A large proportion of all chronic abscesses met with in surgical practice arise in this way. When the abscess opens on the surface, exposing the diseased bone to the air, the process is sometimes spoken of as *open caries*.

It frequently happens that caseation of the inflammatory products or chronic suppuration takes place before the cancellous bone has been completely destroyed in the rarefactive process. The unabsorbed fragments then being cut off from their nutrition perish, and we thus get the condition known as *caries necrotica* or *necrotic caries*. The fragments of dead bone may be of considerable size, forming large sequestra surrounded by carious bone, or may be so small as merely to give a gritty feel to the degenerated granulation-tissue in which they are lying. *Caries necrotica* is frequently associated with tubercle.

General Appearance of Carious Bone.—On examining a macerated specimen of carious bone it will be found to be much more porous and fragile than natural, the cancelli being thinned and the spaces enlarged. Here and there cavities will be seen where the cancelli have been completely destroyed and the spaces have coalesced. In these cavities loose pieces of dead bone may be lying. A fresh specimen shows the following appearances proceeding from the circumference to the centre of the carious patch. The earliest morbid change is increased vascularity of the medullary tissue, which is redder than natural; the next change observed is that the normal fatty or dark-red semifluid marrow has become replaced by pink gelatinous granulation-tissue, and that the cancelli are becoming thinned. Nearer the centre the bony cancelli entirely disappear, and the new tissue becomes opaque and pale yellow from fatty degeneration. In the centre it may form a caseous mass, softening in parts into a thick, curdy, puriform fluid. Even in cases in which there is every reason to believe the process is tubercular, and in which the microscope shows the anatomical appearances of the tubercle follicles, gray granulations are seldom to be recognized. If they are seen they are more likely to be found near the circumference, where they have not yet been concealed by the further inflammatory changes around them. *Caries necrotica* presents the same appearances, with the addition of fragments of dead bone, mixed with the degenerating inflammatory products. If these are decomposing, they will be black or gray in color, if not, they are white. If the process have been very chronic, small patches of opaque white bone may be found, in which calcification has taken place in the inflammatory products filling the cancelli.

In simple or dry caries the same appearances are found, but there is no fatty degeneration. The granulation-tissue maintains its pink gelatinous appearance throughout.

In all cases of caries the neighboring periosteum is swollen and thickened and new bone is formed beneath it. In central caries the compact tissue is early somewhat rarefied.

Statistics of Caries.—Billroth and Menzel, of Vienna, have examined the position of the relative frequency of caries in different bones. In 1996 cases, the numbers were: skull, 161; facial bones, 44; vertebral column, 502; sternum, clavicle, and ribs, 184; bones of shoulder-joint, 28; elbow-joint, 35; wrist and hand, 41; pelvis, 80; hip-joint, 189; knee-joint, 248; ankle-joint and foot, 159; scapula, 4; humerus (shaft), 13; radius, 2; ulna, 4; femur (shaft), 31; tibia, 30; fibula, 2. A classification in regions gives: head and spine, 1034; upper limbs, 185; lower limbs, 720. Hence it appears that, while any bone may be affected with caries, it is most frequently met with in the short and cancellous bones.

SYMPTOMS.—The symptoms indicative of the occurrence of caries are very general, and are not unfrequently, in the early stages, mistaken for those of ordinary abscess or rheumatism. They consist of pain in the bone, sometimes with a good deal of redness and swelling in the soft tissues covering it; abscess at last forms, often of considerable size; and, on letting out the pus, the character of the disease will be recognized, as the bare and rough bone may be felt with a probe, which sinks into depressions upon its surface, which, though rough, yields readily to the pressure of the instrument. The cavity of the abscess gradually contracts, leaving fistulous openings, which discharge pus in varying amounts. The discharge is frequently fetid, unless means be taken to prevent its decomposition. Granules of bone, the minute sequestra from necrotic caries, are often intermixed with it, and it has been shown to contain a considerable amount of phosphate of lime. The fistulous openings are generally surrounded or concealed by high spongy granulations, and the neighboring skin is dusky and inflamed.

These sinuses or fistulae are often long and tortuous. They wind along and around the muscles, the pus finding its way along the lines of least resistance in the intermuscular planes of areolar tissue, the external opening being often situated at a considerable distance, perhaps many inches, from the diseased bone. In these cases a long and flexible probe is required to traverse the sinuosity of the fistulous track so as to reach the bone at its extremity; and here Sayre's vertebrated probe (Fig. 603) is sometimes useful, being flexible and accommodating itself to the windings of the canal. A similar instrument has been devised also by Steele, of Bristol.

The difficulty of draining these long sinuses efficiently, often leads to the accumulation of pus, frequently septic in character, at a certain degree of pressure in the deeper parts, in consequence of which the suppuration may be maintained almost indefinitely, the patient finally perishing from exhaustion, hectic, chronic septic poisoning, or albuminoid degeneration of internal organs.

TREATMENT.—The treatment of caries must be conducted in reference to the constitutional cause that occasions it, the removal of which is the first and most essential element in effecting a cure. If it arise from syphilis, this must be treated; if from struma, the general health must be improved. By the removal of such causes, the disease will often cease spontaneously, and

Fig. 603.—Sayre's Vertebrated Probe

even undergo cure, more especially in young subjects. Hence, it is well not to be in too great a hurry to interfere, by operative means, in caries of the small bones of children. I have often seen cases, especially of caries of the bones of the hands and feet, in which an operation for the removal of the diseased bone was apparently indispensable, recover spontaneously on change of air, and attention to the general health of the child; the disintegrated particles of the diseased bone being eliminated piecemeal.

In the earlier stages of caries, should there be any acute inflammatory symptoms, measures should be taken, by means of appropriate local and constitutional antiphlogistics, to subdue the activity and limit the extension of the disease; and when this has fallen into a chronic state, constitutional alteratives should be employed. Amongst these, cod-liver oil, the iodides, and change of air, more especially to the sea-side when the patient is young, should hold the first place. Counter-irritation is of little avail in these cases in arresting the progress of the disease. By means of blisters, rubbing, and issues, thickening of the periosteum and of the soft structures covering the diseased patch of bone may be lessened, and pain subdued; but the real progress of the osseous disease cannot, I think, be influenced by such means, when once it has passed the earliest stage of inflammatory congestion.

When the disease has lasted some time, and nature seems unable to eliminate the carious bone, all reparative action having ceased, or being inefficient for the restoration of the integrity of the part, an operation becomes necessary.

When the operative procedure is carried out in the diseased part itself it is impossible to be too careful in delaying it until the acute stage of the disease has passed, and the inflammation in the bone and surrounding tissues has become chronic. Unless this be done, the operation is very apt merely to give a fresh impetus to the disease; and should decomposition of the discharges take place, septic osteomyelitis of the affected bone may ensue.

Operations.—The operations practised upon carious bones are of four kinds: consisting either in simple Removal of the Diseased Portion of Bone, in Extension of the Carious Articular End, in Resection of the Whole of the Bone affected, or in Amputation of the Whole Limb.

Before proceeding to the *Removal of the Carious Portion of the Bone* the limb should be rendered bloodless by Esmarch's method, as the operator will then be able to see exactly what he is doing, instead of working in a deep hole filled with blood. The bone is best removed in most cases by means of the gouge. This instrument is especially useful in those cases in which short, thick bones, or the articular ends of the long bones, are affected, without implicating any of the neighboring joints. In applying the gouge, the diseased portion of bone should be exposed by a crucial incision, and, if necessary, its cavity opened by a small trephine. The gouge, fixed in a short, round handle, is then freely applied, and the diseased tissues are scooped and cut out. In order to do this efficiently, it is desirable to be furnished with instruments of different shapes and sizes, so that there may be no difficulty in hollowing or cutting away every portion of bone that is diseased. In many cases Volkmann's sharp spoons may be advantageously substituted for gouges. I have found the *gouge-forceps* (Fig. 311) very useful in clearing away angular fragments and projections of bone. In some cases Marshall's *outletre* (Fig. 304) will be found a very serviceable instrument, clearing away the softened carious bone without risk to the surrounding healthy structures.

In removing carious bone with these instruments, the Surgeon may be sometimes at a loss to know when he has cut away enough. In this he may generally be guided by the difference in texture between the diseased and

healthy bone; the former cutting soft and gritty, readily yielding before the instrument, whilst the latter is hard and resistant; so that, when all the disease is removed, the walls of the cavity left will be felt to be compact and smooth. In some cases, the healthy bone may have been softened by inflammation; should there be any doubt as to the condition of what has been scraped out, it may be solved by putting the *détritus* into water, when, if carious, it will become either white or black, whereas if healthy, but inflamed, it will preserve its red tint. In operating on young children especially, it is well not to have the gouge too sharp, lest the inflamed, but otherwise healthy though somewhat softened bone, be cut away together with that affected by caries. After the operation the cavity must be carefully cleaned to remove any *détritus* or loose fragments that may be left behind. This is best done by means of pieces of sponge held in a pair of polypus forceps. The sponges should be moistened with chloride of zinc (gr. xx to 3j) so as to disinfect the wound thoroughly. All unhealthy granulation-tissue lining the sinuses should be scraped away with a sharp spoon. A few grains of iodoform may be introduced into the cavity and a drainage-tube inserted. The best dressing is iodoform or salicylic wool, applied so as to form a covering about an inch and a half to two inches thick over the wound, and extending at least six inches on each side of it. This dressing may be changed at the end of a week for the purpose of removing the drainage-tube. A similar dressing is then applied, and if the part affected is near a joint, a plaster-of-Paris bandage may be applied over it and left on for a month or six weeks, unless some discharge shows out from beneath it, or the patient complains of pain, or suffers from febrile disturbance. A considerable number of cases have been treated in this way in University College Hospital with the best results. In a considerable proportion the wound has been found completely healed when the second dressing was removed. If the cavity be of very large size, more frequent dressings may be necessary. If the materials for this dressing are not at hand, the wound may be dressed with carbolic oil, glycerine and carbolic acid, terebene and oil, or any other efficient antiseptic application.

Instead of removing the affected bone by means of instruments, Pollock has recommended that it should be dissolved by the application of a strong solution of sulphuric acid. The treatment is carried out as follows: the carious surface or cavity being exposed as before described, a solution of equal parts of strong sulphuric acid and water is applied by means of a glass wash or ear and this may be repeated daily till the whole surface is quite free from diseased bone. In deep cavities a piece of lint soaked in a weaker solution (one part of the acid to five or six of water) may be stuffed in and changed two or three days. The slough resulting may in a day or two more be peeled off with forceps and the application repeated if any diseased bone can still be seen. The treatment is said to be efficacious, and the pain accompanying it is not severe.

When caries affects the articular ends of the bones, as those that enter into the formation of the elbow- or shoulder-joints, it may be so situated as not to admit of removal in the way just indicated, but to require *Excision of the diseased articulation*; this operation we shall consider in a subsequent chapter. When caries involves a bone so extensively that neither of the preceding plans can successfully be put into operation, it becomes necessary

Fig. 104. — Mallet-Osteotome.

to perform either the *Resection* of the whole of the bone if it be of small size, or *Amputation* of the limb, if of greater magnitude or if the neighboring joints be extensively affected. Thus, for instance, resection of the calcis may be required for caries of that bone; while, if the whole of the tarsus be affected, amputation is the only resource.

NECROSIS.

The transition from Caries to **Necrosis** is easy. Caries may be regarded as a condition closely analogous to ulceration of the soft tissues: whilst necrosis must be looked upon as identical with gangrene. Whilst caries, however, chiefly affects the cancellous structure, necrosis is met with in the compact tissue of bone, and occurs far more frequently in the shafts than in the articular ends of the long bones. It is, however, an error to suppose that the cancellous structure is exempt from necrosis; thus in the head of the tibia, or in the os calcis, small masses of necrosed bone are not unfrequently found lying in the interiors of carious or suppurating cavities. Different bones are affected by necrosis with varying degrees of frequency. The tibia at its anterior part is most frequently diseased; the femur in its lower third is also very commonly affected. The lower end of the humerus is not so often necrosed; but not uncommonly the phalanges of the fingers from whitlow, the skull from syphilis, the lower jaw from the emanations evolved in the manufacture of phosphorus matches, and the clavicle and ulna from injury or constitutional causes, are found affected by necrosis.

CAUSES.—The causes of necrosis are very various. We have just seen that it is *Predisposed* to by the structure of particular parts of bone, and is more frequent in some bones than in others. Among the constitutional conditions which predispose to it, we must rank in the first line scrofula and syphilis. Acute febrile disturbance, more particularly scarlet and typhoid fevers, are not unfrequent causes of necrosis in the young. Scarlet fever especially is apt to be followed by pains in the leg and about the knee, which at first appear to be of a rheumatic character, but which speedily run into abscess and are attended by all the symptoms of the most acute form of necrosis.

Most of the local conditions which give rise to necrosis of bone have been already described, and require merely to be mentioned here. Before the age of puberty almost all cases of extensive necrosis of the shafts of long bones are the result of acute diffuse periostitis or acute necrosis (see p. 292). In the cancellous tissue necrosis is sometimes the result of acute osteomyelitis, but more commonly arises from a more chronic form of inflammation, often tubercular, accompanied by cessation of the inflammatory products by which the vascular supply of the affected area is cut off. Acute osteomyelitis following injuries of bone is a common cause, especially after amputations (p. 274), or should the same condition arise without injury (p. 279), the same result takes place. Chronic periostitis and osteitis, when the disease assumes the osteoplastic form, may gradually lead to necrosis by obliteration of the Haversian canals (p. 278).

Sometimes the death of bone results from the extension of inflammation to it from the neighboring tissues, as in some cases of whitlow, or from the destruction of its periosteum by a neighboring abscess.

Syphilitic necrosis arises in three ways: first, from superficial ulceration extending till it reaches the bone and destroys its periosteum; secondly, by the formation of subperiosteal gummata, which finally soften and thus cut off a piece of bone from its vascular supply; and, thirdly, by gradual obliteration of the Haversian canals in chronic syphilitic osteitis.

In all these forms the immediate cause of the death of the bone is the arrest of the flow of blood through it.

In some cases necrosis occurs in old people without any evident cause, being then apparently simply the result of old age. This I have seen occur in the lower ends of the humerus and tibia, giving rise to rapid and usually fatal disorganization of the neighboring joints, or to death from exhaustion after profuse suppuration. This *Senile Necrosis* may be looked upon as the counterpart in the bone of senile sloughing or gangrene in the soft parts.

Traumatic causes frequently give rise to necrosis. Thus the denudation of a bone by stripping off of periosteum, may lead to its death; but, though the bone thus injured often loses its vitality, yet, if the membrane be replaced, as it may be preserved, and even when the bone is exposed, adhesions may take place between it and the neighboring soft parts, or granulations may be thrown out by its surface, which eventually form another periosteum. Necrosis frequently occurs as the result of the detachment and denudation of a portion of bone in cases of bad compound fracture; so also the application of certain irritants, as the fumes of phosphorus, may occasion this disease, and hence it has been found that, in lucifer-match manufactories, necrosis of the lower jaw is a frequent consequence of the acrid fumes that are eliminated, gaining access to the bone through carious teeth, and being applied to the exposed alveoli.

CHARACTERS.—In whatever way it originates, necrosis may affect the outer lamina only of the bone, when it may be called *peripheral*, or the innermost layers that surround the medullary canal may perish, and then it may be termed *central*; or the whole thickness of a shaft, or of the substance of a short bone, may lose its vitality, and it is then spoken of as *total*. The necrosed portion of bone, called the **Sequestrum**, presents peculiar characters, or which its nature may at once be recognized. It is of a dirty yellowish-white color, and has a dull opaque look, and, after exposure to the air, it gradually becomes of a deep brown or black tint; the margins are ragged, and more or less spiculated, and the free surface is tolerably smooth, but its attached surface is very irregular, rough, and uneven, presenting an eroded or worm-eaten appearance. This eroded appearance is very marked in sequestra that form in the interior of the terminal end of the femur in a thigh-stump after amputation, and is well illustrated by Fig. 28, where the lower smooth part is composed of the whole thickness of the bone, whilst the upper rough and spiculated portions consist of the central layers of bone separated from the outer layer, and hence their eroded external surface. When the sequestrum forms in the cancellous tissue, it is usually of a blackish-gray color, and irregular or ovoid in shape.

When the necrosis has been the result of an acute inflammatory process, as osteomyelitis or infective periostitis, the bony tissue of which it is composed has exactly the appearance of a corresponding piece of healthy bone ossified after death. On the other hand, when the death of a piece of bone has been a complication arising during some chronic inflammatory process, the sequestrum bears evidence of the previous disease upon it. Thus, if it result from osteoplastic osteitis, it is denser than natural, it from rarefactive osteitis, as is commonly the case in necrosis of the cancellous tissue, is lighter and more porous than the normal structure, and often eaten out into irregular cavities, or may present patches of calcification in the cancellous spaces.

SYMPTOMS.—The symptoms of necrosis are divisible into three distinct periods. In the first they are those of the disease in consequence of which the death of the portion of bone has taken place, being acute in acute diffuse periostitis, osteomyelitis, chronic in chronic periostitis and osteitis, tubercular

caries, or in syphilitic cases, periostitis or subperiosteal gummata. In the second period the primary disease having ceased, the process of separation of the dead bone from the living takes place with the formation of a suppurating layer of granulation tissue at the expense of the latter, and simultaneously new bone is formed from the periosteum to maintain the rigidity of the part when the dead part becomes loose. In the third period, the dead bone having been expelled or removed, the final processes of repair take place by which the restoration to the proper size and shape of the canal is effected. The particular character of the symptoms depends, however, not only on the stage and cause, but also in a great measure on the seat and the extent of the necrosis. As already stated, the sequestrum may be peripheral, central, or total, perhaps involving the whole thickness of the shaft.

The acute diseases causing necrosis have already been sufficiently described, but a few words are required on some of the chronic forms.

When the necrosis is associated with caries, as in caries necrotica the symptoms are those already described as occurring in that disease, pain like that of rheumatism, and tenderness with gradual enlargement of the affected bone. At a later period chronic suppuration takes place, and the abscess at last points beneath the skin. When this is opened a probe will pass into the carious cavity in which the sequestrum is lying. When the sequestrum is small and central, it may become enveloped with a small quantity of cheesy pus in a dense wall of solid bone. The symptoms are then those of chronic abscess.

Extensive necrosis may occasionally take place without the formation of a drop of pus. Cases of this kind have been described by Sir James Paget under the name of *quiet necrosis*, and by Mottant Baker as *necrosis without suppuration*. The symptoms are those of chronic osteitis and periostitis (p. 285), and the diagnosis can be made only when, all means of treatment having failed, trephining of the bone is undertaken for the relief of the pain. In Baker's case the enlargement exactly resembled a tumor, and as spontaneous fracture finally took place, there seemed no doubt as to the nature of the disease. The real condition was discovered only after amputation at the hip-joint. In these cases the necrosis is due to arrest of the circulation by osteoplastic periostitis obliterating the Haversian canals, and the part necrosed is always the central portion of the compact tissue of the shaft.

Another course taken by necrosis, especially when it follows fever, may be best illustrated by briefly describing three typical cases. The first was a girl aged 14, who complained of persistent pain in the buttock after an attack of rheumatic fever. A hard brawny swelling gradually formed during the following year. It was aspirated but nothing was found, and fears were entertained that it might be a sarcoma. Some weeks after a few drops of pus escaped from the puncture, and on dilating the opening a small sequestrum, about the size of a thumb-nail, was found detached from the side of the pelvis. The second was a man aged about 35, who complained of a slowly growing tumor, about 2½ inches in diameter under the right nipple, that had appeared some months after typhoid fever. He was sent into University College Hospital by an accomplished practitioner as a case of scirrhus of the male breast, and came under the care of Marcus Beck. There was one small enlarged gland in the axilla, and there seemed no doubt about the diagnosis, but to avoid any possibility of error a deep incision was made into the growth, which grated under the knife, and felt and looked like scirrhus. It was accordingly removed, when a small cavity half an inch in diameter was found beneath, containing some caseating granulation tissue; the finger passed from this through the pectoralis major to a small sequestrum on the fifth rib. The third case was a girl, aged about 14, who was sent into the hospital for a tumor, supposed to be an enchondroma, just below

the crest of the ilium. On cutting down on it it proved to be a chronic abscess with exceedingly thick walls, containing a sequestrum about the size of a split pea which had been separated from the ilium. She had recently recovered from typhoid fever.

Separation of the Dead Bone and Formation of Provisional New Bone.

The separation of the dead bone, or its *exfoliation*, is carried out by a process precisely similar to the mode in which a slough in soft tissues is thrown off, the only difference being the time required. Rarefying osteitis is set up in the living tissue where it meets the dead. The details of this process have already been described (p. 270, vol. i.). As the result of it a narrow zone of the living bone is destroyed, and its place occupied by soft vascular granulation-tissue. This process goes on most rapidly in the most vascular parts; thus we see the granulation-layer first completely formed near the periosteum and medullary canal, and gradually advancing from these points till the dead bone is completely separated from the living. If a bone in which a sequestrum is partly separated be uncerated so as to destroy the granulation-tissue, a groove about one twentieth to a quarter of an inch wide will be seen. On the living side of this the bone is porous and its Haversian canals enlarged and gradually condensing. On the dead side the bone retains its normal compact structure. The line between the dead and living is always extremely irregular. The granulation-tissue in contact with the dead bone yields a more or less abundant supply of pus, which, according to B. Cooper, may contain as much as 2 per cent. of phosphate of lime. When the separation is complete the dead bone lies closely surrounded by vascular granulation tissue, and bathed in a certain quantity of pus. If the bone be decomposing and the discharge fetid, the pus will be increased in quantity in consequence of the irritation of the granulation-tissue by the septic products.

When once the dead bone has been detached by the formation of this line of separation, nature takes steps for its ultimate removal from the body. There is no evidence that it, in any circumstances, undergoes absorption to any great extent; although, as Paget and Billroth remark, that portion which remains in contact with proliferating granulations may undergo a certain amount of diminution. That this may be so is rendered more probable by the fact that the ivory pegs used in the treatment of ununited fracture have been found to be partly absorbed after some weeks. The absorption of the margin of the living bone, in the formation of the line of separation, explains the fact that the sequestrum will always be found to be of much smaller size than the cavity in which it is lodged. The ultimate expulsion of the loosened sequestrum is effected by the growth of the granulations below it pushing it off the surface, or out of the cavity in which it lies. When the necrosed bone is *peripheral*, it will be readily thrown off in this way, although it may for a time be fixed and entangled amongst the granulations. When the sequestrum is *intra-medullary* within new or old bone, the process of elimination is necessarily very tardy, and may be difficult or impossible without surgical aid.

The time required for the separation of dead bone varies greatly. When it is superficial and small in size, a few weeks may suffice; but when the leg or the bones, as the femur, the scapula, or the humerus, are affected, the process may be extended over several years, and may terminate in the death of the patient from exhaustion before it is concluded; the constitution being exhausted and worn out by hectic induced by profuse suppuration. Or the disease may fall into a chronic state, the limb becoming rigid, and the tissues much indurated, with fistulous apertures leading down to exposed but attached bone, and thus being a source of constant annoyance and suffering to the patient.

CHAPTER XLVII.

STRUCTURAL CHANGES IN BONE AND TUMORS OF BONE

HYPERTROPHY OF BONE.

True Hypertrophy of Bone, that is to say, increase in size without alteration in form or structure, is very rare. It occurs as the result of excessive use, in common with the enlargement of the muscles inserted into it.

The term **Inflammatory Hypertrophy** is often applied to those chronic inflammatory processes which cause enlargement of a bone, diffused over a considerable part of its length. When the thickened bone is more spongy than natural, the change is termed *Spongy Hypertrophy*; when it is denser, *sclerosis*, or hardening of bone. Spongy hypertrophy occurs in its most marked form in the disease described by Sir James Paget as *ostitis deformans*. Sclerosis is most commonly met with as the result of syphilis or after recovery from chronic osteitis and periostitis in scrofulous subjects. It may affect several bones at the same time; and, in the long bones, may lead to filling up of the medullary and Haversian canals with bony substance, with some thickening of the bone generally. This condition is not recognizable with certainty during life.

Increase of Length of Bones.—Allusion has already been made at p. 285 to the hypertrophy of bone which sometimes follows chronic osteitis. This increased growth of bone, as a result of morbid conditions, has been investigated by Stanley and Paget in this country, and by Langenbeck and others on the continent. It has been observed in connection with necrosis, chronic osteitis, and chronic abscess; and also with chronic hyperemia of the soft parts of a limb. Langenbeck, from his observations, concludes that morbid changes which give rise to irritation and hyperemia of the osseous tissue lead, as long as the growth of bone continues, to an increase both in the length and in the thickness of bones; and that the increase of growth in length affects especially the diseased bones, but may also occur in a healthy bone of the same limb. Sometimes, as Paget has pointed out, the long existence of an ulcer of the integuments in a young person may produce thickening and elongation of the bone. When the femur undergoes elongation in this way, the inequality in length of the limb, unless the opposite limb be lengthened by artificial means, may lead to talipes of the foot of the lengthened limb or to lateral curvature of the spine. The tibia sometimes becomes elongated, while the fibula remains of its normal length; and in such cases the former bone becomes curved. The diagnosis of this condition from the curvature of rickets consists, according to Paget, in the marked elongation; in the absence of thickening of the ends of the bone, which are usually even more nearly equal in size to the shaft than in the natural state, on account of the thickening of the latter; and especially in the fact that "the rickety tibia is compressed, usually curved inwards, its shaft is flattened laterally, and its margins are narrow and spinous; while, in the elongated tibia, the curve is usually directed forwards, the margins are broad and round, the surfaces are convex, and the compression or flattening, if there be any, is from before backwards."

ATROPHY OF BONE.—This term comprises two conditions: one in which the bone is wasted, and another in which an arrest of growth occurs.

Atrophy occurs, as a natural result, in old age; the change that takes place in the lower jaw being a familiar example. In other cases it happens as a consequence of fracture; the nutrient artery of the bone having been torn across, and one of the fragments consequently receiving insufficient vascular supply. Atrophy of bone commonly occurs also from disuse, as is the case in old dislocations. In atrophy, the bone becomes thinner, lighter, and more porous than usual; the compact structure disappearing until a mere paper-like layer may be left, the cancellous spaces being expanded and filled with soft yellow fat. Atrophy of bones is common in general paralysis of the insane. It is often especially marked in the ribs, and is a common cause of fractures, occurring either spontaneously or during the restraint necessarily employed during a maniacal outbreak.

Arrested Growth of bones is an occasional consequence of disease. Its occurrence in rickets will be presently referred to. It may be a result also of various diseases of the epiphyses and joints, of atrophy, or of the resection of the epiphysis in children, and may follow the formation of cicatrices after burns in the neighborhood of joints. The effect of paralysis on the growth of bone varies. It is common to see normal growth of the bones in limbs affected with infantile paralysis, in which the muscles are wasted; while in other cases it has been materially impaired. This probably depends upon whether the epiphyses are properly developed or not.

RICKETS.

RICKETS is a general disease, the most important manifestation of which is an imperfect development of the new tissue of growing bones. It occurs only in early childhood, most frequently appearing during the first or second year of life, though it has been observed as late as the ninth year and is said to exist fully to be congenital.

Causes.—Want of sufficient food and of fresh air, want of cleanliness and light and all the unhealthy surroundings of the overcrowded poor of a large city, are the great causes of rickets. It is rarely met with amongst the wealthy classes, and in the country it is scarcely seen, even among the poor. Insufficient or improper food is undoubtedly the most important of the more special causes of rickets. There is but one proper food for a child during the first nine months of its life, and that is the milk of a healthy woman. The ill-fed mothers amongst the working-classes, exhausted as they often are by repeated childbearing and unnaturally prolonged lactation, are very frequently unable to supply milk of a sufficiently nutritive quality, and thus, even when suckled, the child is but half-fed. Should it be brought up by hand, in order to save expense, flour, or various useless patent preparations of starch are largely used in place of cow's milk. This early feeding with starch before the child is capable of digesting it, is probably the most fruitful cause of rickets. Even if there be no error in feeding, there is reason to believe that the offspring of feeble mothers tend to become rickety. The health of the father has not been shown to exert any influence. Parrot has lately maintained that syphilis in the parents may cause rickets in the child; but, against this there is, as Sir William Jenner has pointed out, one unanswerable argument: in a family of rickety children, as a rule, the younger members are most afflicted, while in inherited syphilis it is exactly the reverse. Tubercle and scrofula have no definite connection with rickets; in fact, they are seldom met with in the same subject. A deficiency of lime in the water of the district has been also stated to be a cause of this disease,

stances, it may spontaneously fracture—an accident that I have seen happen both in the femur and the tibia—or may become shortened or bent. In other instances, again, when the periosteum has been lost by sloughing, new bone does not form (Fig. 597); but as the sequestrum separates, the limb becomes shortened, loose, deformed, and useless.

TREATMENT.—In the treatment of necrosis, the indications to be accomplished are sufficiently simple, though the mode in which they have to be carried out often requires much patience and skill on the part of the Surgeon. In those cases in which the bone is perishing from some chronic progressive disease, as chronic osteitis and periostitis with obliteration of the Haversian canals, or when it is associated with caries, the first point is to remove, if possible, any constitutional or local condition which tends to keep up the disease. Thus, for instance, if it appear to be the result of scrofula or syphilis, those conditions must be corrected. So, again, if it arise in the lower jaw from the fumes of phosphorus, the patient must necessarily be removed from their influence. If it be threatened in consequence of denudation of bone, the best mode of prevention will be to lay down flaps of integument and so to cover the exposed surface. Abscesses should be opened as soon as recognized. In cases of acute infective periostitis the extent of the necrosis is very materially limited by free and early incisions, and in this way the separation of the epiphyses can often be prevented, and the danger of death from exhaustion or pyæmia avoided.

Removal of the Sequestrum.—When all that is possible has been done to arrest the morbid condition to which the necrosis is due, the separation of the sequestrum should be left as much as possible to the unaided efforts of nature. The less the Surgeon interferes with this part of the process the better; for, as has justly been observed by Wedemeyer, the boundaries of the necrosis are known to Nature only, and the Surgeon will most probably either not reach, or he will pass altogether beyond them. Here much patience will be required for many weeks or months; and the utmost the Surgeon can do is to attend to the state of the patient's health, treating him carefully upon general principles, removing inflammatory mischief by appropriate means, opening abscesses as they form in the limb, limiting or preventing the decomposition of the discharges by antiseptic applications, and, at a later period, supporting the patient's strength by good diet, tonics, and general treatment, calculated to bear him up against the depressing and wasting influence of continued suppuration, and of the irritation induced by the disease.

So soon as a sequestrum has been detached from the adjacent or underlying bone the Surgeon must proceed to its removal. In most cases it is sufficiently easy, when the necrosis is superficial, to ascertain that this separation has taken place, as the flat end of a probe may be pushed under the edge of the detached lamina. When, however, the sequestrum is deeply seated, it is not always so easy to be sure that the separation has occurred; though, in the majority of cases, the introduction of a probe through one of the fistulous openings leading to the necrosed bone, and firm pressure exercised upon this, will enable the Surgeon to detect that degree of mobility which is characteristic of looseness. In other cases, however, the sequestrum, though completely free from all osseous connections, still continues to be fixed by the pressure of the surrounding granulations, and by the extension of its spicula into the corresponding cavities of the new osseous case. This especially happens when the sequestrum is central and invaginated, and the clove leading to it are so small that but a limited portion of it is exposed. Here a more careful examination will be required; and its looseness may sometimes be determined by pressing upon it with a probe in a kind of jerking manner, or by introducing two probes through different cloves, at some distance from

one another, and alternately bearing upon the exposed bone with one or other of them. Then, again, if the sound elicited by striking the end of the probe against the sequestrum be a peculiarly hollow one, the detachment of the bone may be suspected. The duration of the disease, also, will probably throw some light upon the probable state of things inside the new case.

The separation of the sequestrum having been ascertained, the Surgeon must adopt measures for its extraction. The part should first be rendered bloodless by Esmarch's apparatus if the disease is situated in a limb. If the necrosis be *peripheral*, all that is necessary is to make an incision down it through the soft parts, either by directly cutting upon it or by slitting up

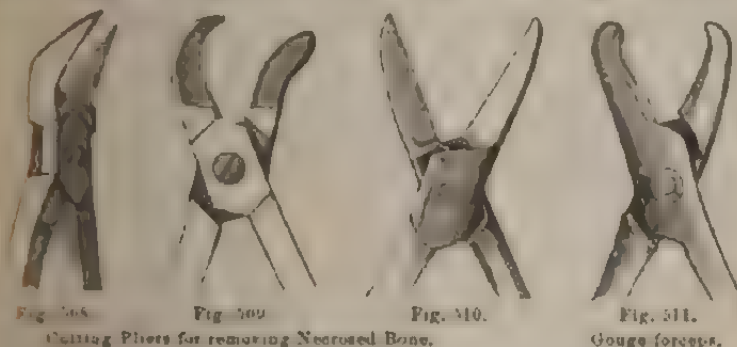

Fig. 308. Fig. 309. Fig. 310. Fig. 311.
Cutting Pliers for removing Necrosed Bone. Gauge forceps.

Fig. 312.—Straight Saw for removing Necrosed Bone.

Fig. 313.—Necrosis-forceps.

and then to remove it with a pair of forceps, or to tilt it off the bed of granulations on which it is lying, by introducing the end of an elevator beneath its edge.

When the necrosis is *central*, the sequestrum being embedded in a new case or covered in by old bone, the operative procedures for its removal are of a more complicated character. The difficulties here consist in some cases in the depth from the surface, and in the obstacle offered to its passage by the soft parts; in others, in the length and magnitude of the sequestrum in proportion to the small size of the cloaca, and in the manner in which it lies in a direction parallel to these openings. In cutting down upon the bone, the

Surgeon must be guided by the direction and the course of the fistulous tracks that lead to the principal apertures in the new case, the incisions being placed in the axis of the limb, and carefully directed away from large bloodvessels and nerves. If the part has not been rendered bloodless, however, the hemorrhage is somewhat abundant, in consequence of the injected state of the tissues furnishing a copious supply of blood, and their rigid condition preventing retraction of the vessels; this, however, may be arrested by a tourniquet, or by the pressure of an assistant's fingers, and will soon gradually cease of itself. The bone having been freely exposed, it will sometimes be found that the cloaca are of sufficient size to allow the ready extraction of the sequestrum. But in the majority of cases, this cannot be done at once, and the apertures must be enlarged, either with the gouge or the trephine, according to the density of the new case, and the amount of room required. Occasionally, when two cloaca are close to one another, the intervening bridge of bone may very conveniently be removed by means of cutting pliers, of different shapes (as in Figs. 508, 509, and 510), or by means of a Hey's or a straight narrow saw having a movable back to stiffen the blade (Fig. 512), and space thus given for the extraction of the sequestrum. Very convenient pliers for this purpose are those represented in Fig. 511. They are made with gouge ends, and hence may be termed *gouge-forceps*. I have found them extremely serviceable in many operations upon the bones. Care, however, should be taken not to remove more of the new case than is absolutely necessary, lest the ultimate soundness of the limb be endangered. In necrosis of the lower end of the femur the bone surrounding the sequestrum is often so peculiarly dense that it can be cut away so as to expose the dead bone only by means of a chisel and mallet, used with considerable force. For the extraction of the sequestrum, the most convenient instrument is a pair of strong necrosis-forceps, well roughened at their extremity, and straight or bent as the case may require (Fig. 513). Occasionally the sequestrum is so shaped and placed that it cannot be seized with this instrument: in these circumstances it will be useful to drive a screw-probe (Fig. 114) into it, by which it may either be extracted, or so fixed as to admit of

Fig. 514. Bone forceps.

seizure and removal by the forceps. In some cases, additional and convenient purchase may be obtained, by fixing a bone-forceps, such as is represented in Fig. 514, firmly into the dead bone. If the sequestrum be too large to be removed entire through the cloaca, it may perhaps best be extracted piecemeal, having been previously divided by passing the points of narrow but strong cutting-pliers into the interior of the bone.

After the removal of the sequestrum, a smooth hollow cavity will be left in the new case, from the bottom and sides of which blood usually wells up freely, issuing abundantly from the vascular bone, and from the granulations lining its interior. Should this hemorrhage be at all troublesome, elevation of the limb and pressure will always arrest it without difficulty. In the subsequent treatment the chief trouble arises from the accumulation

of discharges in the cavity from which the bone has been removed, where they are prone to become excessively foul. To prevent this the cavity should be washed out with chloride of zinc solution (gr. xx to 3i) immediately after the operation and some crystalline iodoform sprinkled in it. It may then be dressed with salicylic or iodoform wool. In this way it can often very soon be brought into a condition to require dressing only about once a week. If these dressings are not at hand, carbolic oil, terebene and oil, or glycerine and carbolic acid, may be applied, and the wound well syringed with Condy's fluid. If the sequestrum have been a long one, and have involved the greater part of the shaft of the bone, it may happen that the new case has not sufficient strength to maintain the limb of its proper length and shape, and that it will bend or break under the action of the forces and weight to which it is subjected. In order to prevent this accident, it will be necessary to put it up in light splints, or in a starched bandage. After the removal of the dead bone, the sinuses will speedily close, and the limb eventually regain its normal size and shape.

Amputation.—If the necrosed bone be so situated that it cannot be removed, occupying too great an extent and continuing to be firmly fixed; and if at the same time the patient's health have been worn down by constant discharge, and symptoms of hectic come on; or if the limb have generally been greatly disorganized by the morbid processes going on in it, recourse must be had to amputation as a last resource. It is especially in the lower third of the thigh bone that these severe forms of necrosis occur, necessitating amputation of the limb. When necrosis affects the flat posterior surface of this bone above the condyles, a special source of danger occurs in the possibility of the sequestrum causing ulceration or wound of the popliteal artery. In cases of this kind, suddenly fatal hemorrhage might occur. Should the hemorrhage, though abundant, not be fatal, what course should the Surgeon adopt in such cases? Should he attempt to ligature the vessel, or should he amputate the limb? The line of practice must, I think, be determined by the condition of the limb itself and by the state of the patient's health. If these be both tolerably good, the limb not too much disorganized, and the powers of the system not too much reduced by hectic, an attempt might be made, by slitting up the sinuses, to expose and secure the popliteal artery at the seat of injury in it, and, by ligaturing it, to save life and limb. But should this attempt fail, as I have known happen, or should it not be thought prudent to make it, owing to the low state of the patient's strength, or the disorganized condition of the limb, amputation must be done without delay. As an rhopathic disease, necrosis of the tibia requiring amputation is rarely met with; but when it is the result of bad compound fractures, or of other serious injuries, removal of the limb may become imperative. In acute necrosis of the lower end of the thigh, or of the shaft of the tibia involving the contiguous joints, and attended by deep and extensive abscess of the limb, amputation is imperative.

Resection of the whole of the necrosed bone may be advantageously performed in such cases as those of the metacarpal and metatarsal bones, or in those of the forearm or leg, where sufficient stability of limb is secured by the remaining bone or bones to leave an useful member. The diseased bone may be thus removed in necrosis of the ungual phalanx occurring from whitlow, when, by the excision of the dead bone, the end of the finger may be preserved; also in necrosis of some of the metatarsal and tarsal bones, or those of the forearm, the inferior maxilla, and the fibula. Subperiosteal resection in cases of acute necrosis has been already alluded to.

The remarks that I have hitherto made apply chiefly to necrosis of the long

bones of the extremities. As there are a few special considerations connected with necrosis of the flat bones, we will now consider these briefly.

Necrosis of the Sternum, Scapula, or Bones of the Pelvis, is an excessively tedious process, there being but very little tendency to the formation of a line of separation and to the detachment of the sequestrum, which will continue bare, rough, and adherent for many years. Should it be so situated that it can be removed, it must be excised, even though not detached. When the ilium and pelvic bones are affected independently of the hip-joint, it is seldom that any operative measure can be employed with advantage; here we must leave the patient to the chance of the bone being at length loosened as to admit of extraction. In some cases, however, if the disease be limited to a portion of the crest of the ilium, or to the tuber ischii, the dead bone may be removed; although in these instances it not uncommonly happens that disease of a similar kind exists elsewhere about the sacrum or spine, that will eventually destroy the patient. In a case in which I removed a portion of the crista ili for necrosis that was apparently confined to that bone, it was found, on the patient dying some weeks afterwards of erysipelas, that the lumbar vertebrae were also diseased. Of late years, considerable portions of the pelvis have been successfully excised for necrosis, as will be more fully mentioned when I come to speak of excision of the hip-joint. The tuber ischii, when affected, may readily be extirpated.

Necrosis of the Cranial Bones is of frequent occurrence as the result of struma or syphilis, or the two conditions conjoined. When met with in children, it is usually strumous, often occurring after measles or scarlet fever; in adults it is usually syphilitic, though by no means invariably so, being sometimes the result of blows in people of otherwise healthy constitution. There are four situations in which necrosis of the cranial bones may occur, viz., in the vault of the skull, the frontal bone, the temporal bone, or in the sphenoid and ethmoid bones. When idiopathic necrosis affects the vault, it is usually syphilitic; when it occurs in the other situations, especially in the temporal bone, it is commonly strumous.

Three forms of necrosis affect the cranial bones. In one case, the outer table is alone affected; this perishes, separates, and exfoliates, granulations spring up from the outer surface of the inner table, and a process of repair is thus established. In the second form of the disease, the whole thickness of the skull necroses, separates from the dura mater and surrounding healthy bone in the usual way, and may be detached in large, irregularly shaped pieces, sometimes of large size, occupying several square inches. In the third form, the necrosis is hard, dry, rough, and pitted or worm-eaten, penetrating through the diploe to the inner table, separating very slowly, and lasting an indefinite period.

Results. In necrosis of the cranial bones, there is always the special danger of extension of inflammation to the membranes of the brain, and the consequent occurrence of effusion within the skull, leading to convulsions, coma, and death. This danger is greatest when the petrous portion of the temporal bone is affected, as the dura mater is continued into some of the canals by which it is perforated. Cerebral complication is less likely to occur when the frontal bone is the seat of disease, more particularly the lower part of this bone, where, by the intervention of the frontal sinuses, the anterior wall is altogether carried away from the inner table, and from all dangerous proximity to the membranes of the brain.

The **Signs** of necrosis of the cranial bones are very obvious. When the vault or forehead is affected, there is tenderness, with some puffiness, and gradual elevation of the scalp into an abscess. When this is opened, the necrosed bone may be felt or seen lying bare, at the bottom of a sinus or

unhealed ulcer. When the petrous portion of the temporal bone is the seat of disease, there will have been earache, followed by profuse fetid discharge from the ear; it is usually secondary to chronic inflammation of the middle ear with perforation of the tympanum, escape of the ossicula auditus, and deafness. When the sphenoid or the ethmoid is affected, deep pains in the head, persistent oedema of the eyelids, and fetid discharge from the nose, will reveal the nature and seat of the mischief.

The *treatment* of necrosis of the cranial bones will vary according to the nature and the seat of the disease. In the dry, pitted variety, exposing and scraping the diseased osseous surface, or the application of a strong solution of sulphuric acid, will often bring about a healthy action, provided the disease has not penetrated too deeply. Should there be reason to think that the inner table has been perforated, it will probably be safer to leave the case to the reparative processes of nature than to trephine. If, however, the anterior wall of the frontal sinus be the seat of the disease, or if the supra-orbital ridge be affected, the dry and rough bone may be safely removed, as I have on more than one occasion had to do, by the application of the trephine in the first instance, and of the gouge in the other case. When exfoliating necrosis of the outer table, or of the whole thickness of the bone, affects the vault of the skull, the loosened plate may readily be lifted off its granulating bed by means of the elevator or forceps, after it has been fairly exposed.

Necrosis of the petrous portion of the temporal bone may be looked upon as an incurable disease, which is usually fatal from septic meningitis. When the sphenoid or ethmoid is the seat of necrosis, little can usually be done by operative interference; though in the latter case portions of sequestrum may sometimes be extracted through the nostrils, and in one extraordinary case under my care in University College Hospital, I removed through the mouth the whole body of the sphenoid bone. The patient, a man aged forty-three, had suffered from syphilis for fifteen years, and from disease of the bones of the nose and upper jaw for three years. The anterior part of the hard palate was destroyed, and it was through the fissure so formed that I removed the bone. The fragment included the sella Turcica, and the roots of the pterygoid processes, but the clinoid processes could not be recognized. The patient had suffered from no cerebral symptoms except occasional headache and some loss of memory. He made a good recovery.

The **Patella** is rarely necrosed. I have, however, met with two instances of primary necrosis of this bone. One case occurred in an elderly woman. The disease came on without any evident external cause, commencing in the anterior part of the patella and gradually implicating the bone, until it became perforated, when rapid suppurative disorganization of the knee-joint ensued, necessitating amputation. The other case occurred after simple fracture of the patella, in a man, and is described at p. 604, vol. i.

Ribs.—When the ribs are necrosed, abscesses and sinuses will often form to a considerable extent on the side of the chest. These must be laid open, and the diseased portion of bone scraped away by the gouge. In doing this, care must of course be taken that the adjacent intercostal space be not punctured by an unfortunate slip of the instrument—an accident that is best avoided by protecting the gouge well with the finger.

CHAPTER XLVII.

STRUCTURAL CHANGES IN BONE AND TUMORS OF BONE

HYPERTROPHY OF BONE.

True Hypertrophy of Bone, that is to say, increase in size without alteration in form or structure, is very rare. It occurs as the result of excessive use, in common with the enlargement of the muscles inserted into it.

The term **Inflammatory Hypertrophy** is often applied to those chronic inflammatory processes which cause enlargement of a bone, diffused over a considerable part of its length. When the thickened bone is more spongy than natural, the change is termed *Spongy Hypertrophy*; when it is denser, *sclerosis*, or hardening of bone. Spongy hypertrophy occurs in its most marked form in the disease described by Sir James Paget as *osteitis deformans*. Sclerosis is most commonly met with as the result of syphilis or after recovery from chronic osteitis and periostitis in scrofulous subjects. It may affect several bones at the same time; and, in the long bones, may lead to filling up of the medullary and Haversian canals with bony substance, with some thickening of the bone generally. This condition is not recognizable with certainty during life.

Increase of Length of Bones.—Allusion has already been made at p. 285 to the hypertrophy of bone which sometimes follows chronic osteitis. This increased growth of bone, as a result of morbid conditions, has been investigated by Stanley and Paget in this country, and by Langenbeck and others on the continent. It has been observed in connection with necrosis, chronic osteitis, and chronic abscess; and also with chronic hyperæmia of the soft parts of a limb. Langenbeck, from his observations, concludes that morbid changes which give rise to irritation and hyperæmia of the osseous tissue lead, as long as the growth of bone continues, to an increase both in the length and in the thickness of bones; and that the increase of growth in length affects especially the diseased bones, but may also occur in a healthy bone of the same limb. Sometimes, as Paget has pointed out, the long existence of an ulcer of the integuments in a young person may produce thickening and elongation of the bone. When the femur undergoes elongation in this way, the inequality in length of the limb, unless the opposite limb be lengthened by artificial means, may lead to talipes of the foot of the lengthened limb or to lateral curvature of the spine. The tibia sometimes becomes elongated, while the fibula remains of its normal length; and in such cases the former bone becomes curved. The diagnosis of this condition from the curvature of rickets consists, according to Paget, in the marked elongation; in the absence of thickening of the ends of the bone, which are usually even more nearly equal in size to the shaft than in the natural state, on account of the thickening of the latter; and especially in the fact that "the rickety tibia is compressed, usually curved inwards, its shaft is flattened laterally, and its margins are narrow and spinous; while, in the elongated tibia, the curve is usually directed forwards the margins are broad and round, the surfaces are convex, and the compression or flattening, if there be any, is from before backwards."

ATROPHY OF BONE.—This term comprises two conditions: one in which the bone is wasted, and another in which an arrest of growth occurs.

Atrophy occurs, as a natural result, in old age; the change that takes place in the lower jaw being a familiar example. In other cases it happens as a consequence of fracture; the nutrient artery of the bone having been torn across, and one of the fragments consequently receiving insufficient vascular supply. Atrophy of bone commonly occurs also from disuse, as is the case in old dislocations. In atrophy, the bone becomes thinner, lighter, and more porous than usual; the compact structure disappearing until a mere paper-like layer may be left, the cancellous spaces being expanded and filled with soft yellow fat. Atrophy of bones is common in general paralysis of the insane. It is often especially marked in the ribs, and is a common cause of fractures, occurring either spontaneously or during the restraint necessarily employed during a maniacal outbreak.

Arrested Growth of bones is an occasional consequence of disease. Its occurrence in rickets will be presently referred to. It may be a result also of various diseases of the epiphyses and joints, of atrophy, or of the resection of the epiphysis in children, and may follow the formation of cicatrices after burns in the neighborhood of joints. The effect of paralysis on the growth of bone varies. It is common to see normal growth of the bones in limbs affected with infantile paralysis, in which the muscles are wasted; while in other cases it has been materially impaired. This probably depends upon whether the epiphyses are properly developed or not.

RICKETS.

RICKETS is a general disease, the most important manifestation of which is an imperfect development of the new tissue of growing bones. It occurs only in early childhood, most frequently appearing during the first or second year of life, though it has been observed as late as the ninth year and is said occasionally to be congenital.

Causes.—Want of sufficient food and of fresh air, want of cleanliness and light, and all the unhealthy surroundings of the overcrowded poor of a large city are the great causes of rickets. It is rarely met with amongst the wealthy classes, and in the country it is scarcely seen, even among the poor. Insufficient or improper food is undoubtedly the most important of the more special causes of rickets. There is but one proper food for a child during the first nine months of its life, and that is the milk of a healthy woman. The distal mothers amongst the working-classes, exhausted as they often are by repeated childbearing and unnaturally prolonged lactation, are very frequently unable to supply milk of a sufficiently nutritive quality, and thus, even when suckled, the child is but half fed. Should it be brought up by hand, in order to save expense, flour, or various useless patent preparations of starch are largely used in place of cow's milk. This early feeding with starch before the child is capable of digesting it, is probably the most fruitful cause of rickets. Even if there be no error in feeding, there is reason to believe that the offspring of feeble mothers tend to become rickety. The health of the father has not been shown to exert any influence. Parrot has lately maintained that syphilis in the parents may cause rickets in the child; but, against this there is, as Sir William Jenner has pointed out, one unanswerable argument: in a family of rickety children, as a rule, the younger members are most affected, while in inherited syphilis it is exactly the reverse. Tubercle and scrofula have no definite connection with rickets; in fact, they are seldom met with in the same subject. A deficiency of lime in the water of the district has been also stated to be a cause of this disease,

but this is evidently not the case, for rickets is far more common in London, which is supplied with water containing a considerable amount of lime, than in Glasgow, where the water contains merely a trace.

Symptoms.—These may be divided into general symptoms and those referable to the changes in the bones. The *general symptoms* are the following: the child may be thin, but is more often apparently well-nourished, sometimes very fat. Its mucous membranes are pale, but the cheeks are often redder than natural. On careful examination, however, with a lens, this will be seen to be caused by a network of dilated capillaries in the true skin. A most characteristic sign is profuse sweating of the forehead when the child is asleep, the rest of the body often being at the same time hot and dry, though the thermometer rarely shows any marked elevation of temperature. There is often general tenderness of the body, so that any handling is painful; partly in consequence of this and partly from the heat of the body, the child kicks off its bed-clothes at night, so that it is sometimes impossible to keep it covered, unless it is made to sleep in flannel drawers and a jersey. The digestion is often good, but there is a tendency to attacks of gastric catarrh, with a furred, white tongue, and perhaps vomiting. The motions are clay-colored and offensive. Flatulence is common, and owing to the weakness of the muscles, which is often a marked effect of rickets, the child usually becomes pot-bellied. The spleen is frequently enlarged, and, in some cases, the liver also. The urine presents, as a rule, nothing characteristic. It may contain an excess of phosphate of lime, but this is not the result of softening of the bones, but evidence of imperfect assimilation.

The *changes observed in the bones* appear early in the disease. They consist of enlargement of the articular ends, most marked at the points of junction of the shaft with the epiphyses; in consequence of which the joints appear to be swollen. The enlargement is also especially marked at the junction of the ribs with their cartilages, which form prominent, rounded swellings, felt and sometimes clearly seen through the skin, giving rise to the appearance which has been termed the "rickety rosary." At a later period, owing to the softness of their structure, the bones bend, giving rise to various characteristic deformities. Humphry and Langenbeck have called attention to the want of growth in length often observed in rickets. Humphry says that the humerus and femur are about one-fourth shorter in rickety subjects than in healthy individuals of the same age. The most important deformities arising in different parts are the following: The *head* early appears large, the forehead being especially protuberant, and the face small. The fontanelles, especially the anterior, are very slow in closing; the bones of the skull may be thickened, forming prominent ridges on each side of the sutures, though occasionally in the occipital they are unduly thin. The *spine* in young children usually presents one long curve backwards from the lower cervical region to the coccyx, with a compensating curve forwards in the neck. In older children there may be merely exaggeration of the normal curves. The *chest* presents very characteristic deformities; the sternum projects somewhat forwards, with a deep depression on each side, caused by the sinking in of the soft, newly formed part of the ribs at their anterior extremities. The deformity is commonly termed "pigeon-breast." The depression is less on the left side, as the ribs are supported by the heart. The lower ribs are pushed outwards by the abdominal viscera. The angles of the ribs are less obtuse than natural. The *clavicles* show merely an increase of the normal curves. The *humerus* is usually bent outwards at the insertion of the deltoid; the *bones of the forearm* are bent outwards in the lower third. The *pelvis* is narrowed from before backwards, more especially

if the deformity commences before the child has learned to walk. The femur presents a single long curve forwards. The tibia and fibula are bent forwards and outwards, or forwards only in their lower thirds. The deformities here mentioned are the most common, but other varieties may be met with. As the child becomes older it frequently becomes knock-kneed or bow-legged.

Dentition is usually much delayed. This is an important symptom, and it is, therefore, necessary to remember the dates at which the teeth should appear. This may be easily done by the following formula, which is accurate enough for clinical purposes. Taking the teeth in anatomical order, commencing with the central incisor, they appear at the following dates in months, 7, 9, 18, 12, 24.

Progress and Prognosis.—Under proper treatment rickets can usually be cured. The bones then rapidly become solid and firm, and remain permanently fixed in their abnormal shape. The concavities of the curves become partly filled up to give the bone the necessary strength, while absorption takes place laterally to preserve lightness. This is often very marked in the femur, the antero-posterior diameter of which may be double the transverse. After recovery from rickets there is frequently early union of the epiphyses, by which the whole body is stunted. Muscular development is, however, often good, and the patient may eventually become sufficiently powerful.

Rickets infinitely rarely causes death directly, but by impairing the power of coughing it indirectly causes the fatal result in a considerable proportion of cases of bronchitis in children.

Pathology.—Beyond the fact that the red corpuscles have been found deficient in number, examination of the blood has thrown but little light on the disease. The nature of the enlargements of the liver and spleen are somewhat doubtful and require further investigation.

In the bones the essential features of the morbid process are, first, an exaggeration of the processes immediately preparatory to the development of true bone; secondly, an imperfect conversion of this preparatory tissue into true bone; and, thirdly, a great irregularity of the whole process. In rickets there is a growth of soft bone, but no softening of healthy bone, such osseous tissue as has been developed before the disease commenced remains unchanged, unless absorbed in the process of the formation of the medullary canal. The pathological appearances are best studied on a longitudinal section of a long bone. In normal ossification a thin, bluish line is seen between the unaltered cartilage and the newly formed bone; in this the proliferation of the cartilage corpuscles is taking place preliminary to the formation of bone. In rickets this line is much thinner than natural, and irregular processes project from it into the cartilage of the epiphysis. The process is wanting in the regularity observed in normal ossification. The proliferating cartilage-cells are heaped irregularly together, and patches in which calcification of the matrix is taking place, are met with, scattered here and there. The vascular medullary spaces also which normally penetrate in an even line into the proliferating layer of cartilage show the same want of regularity in their development. Some will be found projecting an eighth of an inch or more in advance of the others into the unaltered cartilage. These spaces are lined, as in normal bone, with osteoblasts, and bone is formed from them, but the osseous tissue thus produced is softer than natural, and cartilage-cells unaltered, or merely calcified, may be found embedded in it. Beneath the periosteum, especially at the line of junction of the epiphyses with the shaft a thick layer of reddish, vascular, spongy bone is found. Microscopic examination shows that the osteoblastic layer beneath

the periosteum is greatly increased in thickness; the osteoblasts are numerous, but the osteogenic fibres between them are imperfectly developed and lime salts are but scantily deposited; the resulting structure is therefore softer than natural.

Treatment.—In the treatment of rickets our first endeavor must be to remove those conditions which are known to cause the disease. The child must be as much as possible in the open air and should, if possible, be sent into the country. It must be put to sleep in a bed by itself to insure fresh air during the night. If it kicks its clothes off, it must be made to sleep in loose flannel drawers and a jacket, to avoid the risk of catching cold. A bath should be given, of tepid salt water in winter and cold in summer, every morning and evening, or at least once daily. The diet should be carefully regulated. Before seven months it should consist of nothing but milk; the mother's milk is the best if she be in a state of health to suckle her child, if not, the best cow's milk must be given, diluted at first with one-quarter of its bulk of warm water and sweetened with a little sugar. Lime-water may be added if the child vomits or passes undigested milk with its stool. After the child has passed the seventh month a small quantity of properly prepared starch food may be added to the diet, but the supply of milk must not be diminished; at least two pints should be given daily. Underdone meat pounded into a pulp in a mortar, or the juice of raw meat may also be given.

The only remedies that are of any service in rickets are iron and cod-liver oil, the former being the more important. They may be given together—one drachm of steel wine and the same quantity of the oil being taken three times a day *immediately after food*. This treatment must be continued for many months. An occasional dose of rhubarb and soda, or compound liquorice powder may be necessary, and if the tongue be very furred a small quantity of gray powder may sometimes be added. It is of much importance in preventing deformity in these cases not to allow the child to walk or stand much, but to let it take exercise in donkey-panniers or hand-chairs, and to support those limbs that have a special tendency to bend, with properly constructed steel supports, which will be found of much use, provided they are not too heavy, and do not interfere with the action of the muscles. Methodical friction also should be employed to stimulate the muscles.

Combination of Rickets and Scurvy.—Attention has lately been drawn by T. Smith, Cheshire, and T. Barlow, in this country, and Moller and others in Germany, to a disease occurring in young children which is characterized by the following symptoms: after a few days' illness, somewhat sudden swelling takes place, evidently in connection with the bones, usually in the lower extremities, but sometimes also in the upper limbs. Of all bones the femora are most frequently affected, but most commonly the swelling is not limited to one bone. There is subcutaneous edema, varying in amount. Acute tenderness forms a most prominent symptom, and the slightest movement evidently causes severe pain. The limbs consequently lie motionless, a condition which has been termed "pseudo-paralysis." The swelling of the bones is usually most marked near the ends of the shafts, and in extreme cases the epiphyses are found to be separated. Other bones often become affected subsequently to the first appearance of the disease. There is usually some elevation of temperature, but it seldom exceeds 101.5° F. Spontaneous gum are met with in about half the cases; purpura, hæmaturia, and subconjunctival hæmorrhage, have also been noted. The child soon becomes extremely anæmic, and, if not properly treated, rapidly emaciates and dies.

The fatal cases, when examined after death, have shown that the pain and swelling are due to a copious extravasation of blood beneath the periosteum.

stripping it widely from the bone. The disease has been described by German writers as "acute rickets," but Barlow, who has carefully analyzed 22 cases, states that in three the signs of rickets were very pronounced, in seven moderately well marked, in nine slight, and in three absolutely wanting. He therefore concludes that the scurvy is the essential part of the disease, the rickets being more or less accidental, and at most favoring the occurrence of the subperiosteal hemorrhages. In every case the disease seems to have been the effect of improper feeding, chiefly an insufficient supply of milk in infants, and want of vegetables in older children. Barlow therefore suggests the name of "infantile scurvy" for the disease. The treatment is usually successful if the disease be recognized in time. Milk, lime-juice, and fresh vegetables, with plenty of fresh air, soon relieve the symptoms.¹

MOLLITIES OSSUM. OSTEOMALACIA.

A most destructive and dangerous disease of the bones, characterized by softening and fragility of the osseous structure, is occasionally met with. This affection has been studied with much attention by Curling, Solly, Stanley, MacIntyre, and Litzmann; and it is principally from their labors that we are acquainted with the chief facts relating to it.

In this disease the bones are bent, or their shafts broken in various parts of the body. Occasionally, though very rarely, only one is fractured; but in other cases, as in Tyrrell's, there may be as many as twenty-two fractures, or, as in Arnott's, thirty-one. These fractures are unattended by any attempt at the formation of callus. The body becomes singularly and distressingly distorted. On examining the bones after death the periosteum is seen to be usually redder and more vascular than natural. A section of the bone can be readily made with a knife, the osseous tissue feeling soft and gritty as it is cut. The medullary canal of a long bone is increased in diameter, the spaces of the cancellous tissue are enlarged by coalescence, the destruction of the bony trabeculae, and the compact tissue is more spongy than natural, from widening of the Haversian canals. However advanced these changes may be, there is always a thin unaltered layer of compact bone immediately beneath the periosteum. The enlarged cancellous spaces and Haversian canals are filled with an oily, red, granular, semifluid substance. Microscopic examination shows, according to Cornil and Ranvier, that the fat cells of the medulla have disappeared to a great extent, and their place is occupied by small round cells, spindle cells, and some flattened ones. Hemorrhages into the medullary substance are common. In the later stages the contents of the medullary spaces contain a substance resembling the spermic pulp in appearance, and the cells contain numerous pigment-granules derived from the extravasated blood. The trabeculae of bone appear as if they had been acted on by acid. The lime-salts have disappeared from the layers of bone nearest the vessels, leaving the tissue transparent, but still showing the bone-corpuscles just as in bone artificially decalcified. This process gradually advances, and is followed by absorption of the decalcified matrix, while the corpuscles either perish or mingle with the cells of the altered medullary substance.

The term *acule molities* is sometimes incorrectly applied to the atrophy of the age. In this, however, the enlarged spaces are filled with yellow fat, and not with the characteristic tissue just described.

In chemical composition, the diseased bone has been found by Leeson to be

¹ For further information on this interesting disease the reader is referred to a paper by Dr. T. Barlow, in the *Medical-Chirurgical Transactions*, vol. lxxvi, p. 159.

composed of 18.75 parts of animal matter, 29.17 of phosphate and carbonate of lime, and 52.08 of water in every hundred parts.

Cause.—The cause of the complaint is obscure. It has been stated that it is sometimes connected with a rheumatic tendency; as, in every case recorded, the affection has been preceded or accompanied by severe pains, resembling rheumatism. In some instances the patients have been affected with syphilis. It most commonly, though not invariably, occurs in females, as pointed out by Kilian; and in a majority of cases it appears to have a connection with the childbearing state. Among 131 patients whose histories have been collected by Litzmann, of Kiel, there were 85 females, in whom the disease either appeared during pregnancy or was modified in its course by this condition. Of the remaining 46 patients, 35 were females, and 11 males. It most generally attacks adults, having been observed in few cases under the age of 20; and it may occur even at very advanced age.

The **Seat of the Disease**, according to Litzmann, varies according as it occurs within the childbearing period or independently of this. In 85 childbearing women, the whole skeleton was affected in 6 cases only, and all bones except those of the head in two; while in 46 other cases, all parts of the skeleton were diseased in 21, and all the bones except those of the head in six. The percentage of the occurrence of the disease in various parts is shown in the following table:

	85 child-bearing women	46 other cases.
Pelvis	50	87
Spinal Column	54	87
Chest	31	84
Lower Limb	17	78
Upper Limb	12	62
Head	8	52

In childbearing women the disease appears to have a remarkable predilection for the pelvis; it is probable, however, that a careful examination of all the bones has not been made in all cases.

State of the Urine.—In all cases that have been recorded, the urine has been found to contain large quantities of earthy matter. Solly pointed out that this is phosphate of lime, which has been absorbed from the bone, and thrown out by the kidneys in the urine; and sometimes the elimination of this matter is so abundant that it forms, as in one of the cases which he relates, a calculus clogging up the interior of the kidney. In MacIntyre's case, the earthy matters of the bone appear to have been, in the first instance, absorbed, and carried off from the kidneys by the urine; but afterwards an animal matter, of a peculiar and apparently previously undescribed character, was discharged in abundance.

Symptoms.—These are, in the early stages, extremely obscure and insidious. The patient complains, in the first instance, of wandering pains about the limbs and trunk which assume usually a rheumatic character, though they have been observed to be of a much more severe, persistent, and intractable nature than those that occur in any form of rheumatism. The patient becomes debilitated, unfitted for exertion, and emaciated. Spontaneous fracture now occurs in some bones under the influence of the most trivial causes; others become bent, and the body consequently greatly misshapen and distorted. The deformity of the pelvis is a frequent cause of difficult labor, often necessitating Cæsarean section, or Parrot's operation. The acetabula are approximated by the weight of the body pressing on the head of the femora; thus the oblique diameters are diminished, while the

pubes is carried forward, the horizontal rami often coming nearly in contact. The urine presents some of the abnormal characters above described, and death usually eventually results from general exhaustion.

Diagnosis.—The diagnosis of this affection has to be made in the early stages from *rheumatism*. This is not always easy, and, indeed, is at first impossible, but after a time, when the peculiar phosphatic condition of the urine and the fragility or distortions of the osseous system manifest themselves, the true nature of the affection becomes apparent. With *rickets* it cannot possibly be confounded, as rickets is a disease of childhood, and osteomalacia is peculiar to adult or advanced life.

Treatment.—With regard to treatment, but little can be done; the administration of tonics, and a general supporting plan of treatment, may arrest for a time the progress of this terrible affection; but when once it is declared, it usually progresses from bad to worse, and at last destroys the patient. Opium may be employed to allay the pain, and in MacIntyre's case some temporary advantage seemed to result from the administration of arsenic; but no remedy has appeared to exercise any continuous advantage in this complaint. Cases have however been recorded in which, after very extensive softening of the bones, complete recovery has taken place.

TUMORS OF BONE.

Exostosis.—By exostosis is meant the growth of a bony tumor from some of the osseous structures of the body. The causes that immediately give rise to this disease are usually extremely obscure. There can be no doubt that in some instances it is hereditary; but, in general, it occurs without any distinct or appreciable exciting cause. It is met with chiefly in the young, developing about the age of puberty. Exostosis appears to originate in two ways; being either primarily formed as true bone developing from periosteum, or being the result of the ossification of an enchondroma.

Exostoses are of two kinds—the one hard and compact, the other softer and more spongy. The hard, or **Ivory Exostosis**, is usually single, rarely multiple. It is developed from fibrous tissue, but in structure differs both in appearance and composition from normal bone. It is extremely compact and white, having a section closely resembling that of ivory, but possessing a true bony structure, Haversian canals, lacunæ, and lamellæ. In chemical composition, it is found to differ from healthy bone in containing more of the phosphate and less of the carbonate of lime, and also in the proportion of animal matter being smaller. This kind of exostosis grows principally from the flat bones, and lower jaw, and, as it is generally of small size, seldom produces much inconvenience, unless it project into and compress important parts. Thus, Choquet relates the case of a tumor of this kind growing from the pubic bone, and perforating the bladder; and it is occasionally found to project into the orbit, or from the inner table of the skull, upon the brain. When exostosis is left to itself, it may become stationary after a time. In some instances it has been known to necrose, and to slough away, as it were, from the parts in which it has been situated. Of this termination Hilton and Bower relate instances.

Ivory Spongy or Cancellous Exostoses grow more rapidly, often attain a considerable size, and are very commonly multiple. When multiple, they are then frequently symmetrical in their arrangement, and are occasionally hereditary through several generations. Exostoses of this form are developed from cartilage. They commence almost invariably at the line of junction of an epiphysis with the shaft, and usually before puberty. When they appear at a later period, it has been suggested that they arise from a portion

of the cartilage of the epiphysis that has escaped ossification. When growing they are covered with a thin layer of cartilage, but should this become completely ossified, growth ceases and the tumor remains stationary. They are then composed of a thin layer of compact tissue surrounding ordinary cancellous bone; opposite the base of the tumor the normal compact tissue is wanting, so that the cancellous tissue of the tumor is continuous with that of the bone from which it is growing. The exostoses of young subjects thus frequently cease to increase when general growth comes to an end. Those commencing after that time show more continuous growth, and more urgently require surgical interference. Spongy exostoses are usually pedunculated; they are irregularly lobulated on the surface, sometimes resembling the head of a cauliflower.

Their most common seats are the lower end of the femur, the upper end of the tibia, and the upper end of the humerus. Their structure has been described and figured with Tumors (vol. i. p. 950).

The *Symptoms* of exostosis are simply those produced by a hard and slowly growing tumor, connected with a bone and pushing forwards the soft parts covering it. In many cases it produces serious inconvenience by its pressure, either upon neighboring organs or mucous canals; or it may occasion ulceration of the skin lying above it. In some cases, exostosis of a long bone may be connected with an arrest of development of the bone from which it springs. Thus I have seen the lower third of the ulna completely arrested in its development by the formation of the exostoses at the lower part of the middle third, the bone being permanently shortened and dwarfed below this point.

Treatment.—If an exostosis be so situated as to occasion inconvenience or deformity, it will be necessary to remove it; and, as it is a local disease, there is no fear of its return, provided this be fully done. If, however, the whole of it be not taken away, it may grow again; and Stanley accordingly recommends that if it be so situated, as upon the skull, that its base cannot be extirpated, potassa fusa or nitric acid should be applied to the part that is left, so as to produce exfoliation of it. The removal of these tumors is best effected by a Hey's or a chain saw, or cutting pliers, or a chisel and mallet. In some situations, as when close upon joints, or springing from the cervical vertebrae, they cannot be interfered with; and in other cases, as occasionally happens in the neighborhood of the orbit, their density and hardness may be such that the saw can scarcely work its way through them. There is one variety of exostosis which deserves special attention. It is that which springs from the upper surface of the ungual phalanx of the great toe. It forms a small round mass, usually about half as large as a cherry, projecting under or beyond the nail, and giving rise to much pain and inconvenience in walking. Dupuytren, who first described this peculiar variety of the disease, has pointed out the treatment proper for it, which consists in exposing it by a double elliptical incision, and cutting it off with the scalpel, or a small pair of pliers, without amputating the toe.

ENCHONDROMATA OR CARTILAGINOUS TUMORS OF BONE are often met with. These have already been described when speaking of enchondroma and its pathology (p. 947, vol. i.), and need not, consequently, be more than alluded to here. They usually require resection or amputation of the affected bone, according to the attachments and size of the growth.

FIBROMA OF BONE.—Fibromata are not common in bone; when they do occur they spring from the periosteum. The situation in which they are most frequently met with is the base of the skull, from which they project downwards into the pharynx and posterior nares, forming the disease known

as fibrous polypus of the nose (*vide* Diseases of the Nose). They are also occasionally met with in connection with the jaws.

CYSTIC TUMORS OF BONE are extremely rare, if we exclude those met with in the jaws, which arise in connection with the teeth, and those in which the cysts are merely an accidental formation in a solid tumor. The cystic tumors described by the older writers under the name of *Spina Ventosa* are always sarcomatous growths in which cysts have developed.

Nelaton describes simple cysts of bone containing a clear or reddish serous fluid, and lined with a smooth membrane having the appearance of a serous membrane, as being occasionally met with in the long bones. He states that the cysts may be unilocular or multilocular. He describes but one case as having come under his observation. The tumor occupied the femur, from the trochanter to one inch from the condyles, expanding the whole shaft to a great size. It was composed of an agglomeration of cysts, mostly about the size of a walnut, and separated from each other by bony septa. The cysts were filled with reddish serum. He states that two similar tumors have been recorded, one by Breschet and one by Travers.

The chief symptom is a slow and almost painless enlargement of the affected bone, forming a smooth, round, or oval growth. The skin covering it is of normal color. When a certain size has been attained, so that the shell of bone is expanded into a very thin lamella, and before it is perforated, pressure on the tumor occasions a peculiar crackling or rustling noise, like that produced by pressing together a broken egg-shell, or the crackling of tin-foil. Under this, the elasticity or even semifluctuation of the tumor may be felt. This fluctuation is particularly marked after a time, when the osseous envelope has become still more expanded, or is partially or wholly absorbed. When the shell of bone becomes very thin, spontaneous fracture may take place.

Cysts of the jaws will be more fully described with the diseases of those parts.

Treatment.—When the tumor is very large, removal of the affected bone may be necessary, but if it be of moderate size, so as not to have materially affected the integrity of the bone, it may suffice to remove one side of the wall of the cyst by the trephine or by excision, and then the cavity may be allowed to granulate, and its walls to contract. This plan has proved especially successful in some of the cystic tumors of the lower jaw; and I have practiced it with success in a small cyst forming in the outer condyle of the humerus.

HYDATIDS.—Cavities are occasionally, but very rarely, found in bones, in which large numbers of hydatids are lodged; according to Stanley, both the *echinococcus* and the *cysticercus cellulose* have been found in this tissue, but most frequently the former. In these cases a cyst forms in the bone, which becomes thin and expanded, resembling the ordinary fluid cystic tumor, but which, on examination, is found to contain the parasite. The *Treatment*, as Stanley observes, must depend on the situation and extent of the disease; if it be a long bone that is affected, and it be much expanded, recourse must be had to amputation; if it be a flat bone, the cyst-wall must be scooped out, and the cavity dressed from the bottom with stimulating applications, so that it may fill with healthy granulations.

SARCOMATA OF BONE—PRIMARY MALIGNANT TUMORS OF BONE.—It is now generally recognized that true cancer never originates in bone, and that the tumors formerly classed as primary encephaloid or scirrhus cancer of bone, osteo-cancer, osteocephaloma, etc., all belong to the class of sarcomata. The fact that there has not been a single well-authenticated case of primary cancer of bone recorded since the distinction between carcinoma

and sarcoma was clearly established, is strong evidence in favor of the view that all true cancer commences in connection with preëxisting epithelium. It is only in such bones as the superior maxilla, and those in connection with the mucous membrane lining the cavities of the face, that true cancer is commonly met with; and here the osseous tissue is involved only by extension of the growth, the primary seat of the disease being the mucous membrane.

The subject of sarcoma of bone has been very thoroughly investigated by S. Gross, of Philadelphia, and by H. T. Butlin, of London, and much light has been thrown by them upon the clinical and pathological features of this disease. For the purpose of classification, sarcomata of bone are divided, first into *central*, springing from the cancellous tissue of the medullary canal, and *periosteal*, *subperiosteal*, or *peripheral*, arising on the surface of the compact bone; secondly, they are subdivided according to the structure of the growth, into *spindle-celled*, *round-celled*, *mixed spindle- and round-celled*, and *myeloid*.

Gross makes a separate division for osteoid or ossifying sarcoma, and separates cartilaginous tumors entirely, placing them in another group. Butlin classes ossifying sarcomata and chondro-sarcoma, according to the form of the cells, spindle, round, or mixed, met with in the growing margin of the tumor. The microscopic structure of these various forms of sarcoma has been already described in the chapter on Tumors, vol. i. p. 961. Gross gives the following as the relative frequency of the different forms of sarcoma among the 165 cases affecting the long bones which formed the basis of his paper. Central myeloid sarcoma, 70; periosteal ossifying sarcoma, 45; central spindle-celled sarcoma, 16; periosteal round-celled sarcoma, 13; central round-celled sarcoma, 12; periosteal spindle-celled sarcoma, 2. Of all forms of sarcoma, out of 149 cases, 87 occurred in males and 62 in females; and of 147 in which the age was ascertained, 110 occurred before

Fig. 515. Cells from Spindle-celled Sarcoma Tumor of Scapula: First Recurrence.

all forms of sarcoma, out of 149 cases, 87 occurred in males and 62 in females; and of 147 in which the age was ascertained, 110 occurred before

Fig. 516. Ossifying Spindle-celled Sarcoma, Tumor springing from the Scapula.

Fig. 517. Microscopic Characters of the Tumor in its Second Recurrence, Multinucleated Myeloid Cells.

30. The central spindle-celled sarcoma was the only form that Gross found to occur more frequently after 30 than before. In almost half the cases the

disease was attributed to injury. The various long bones were affected in the following order: femur, 67; tibia, 46; humerus, 25; fibula, 13; ulna, 7; radius, 6; ulna and radius, 1. The following table, showing the malignancy of the various forms of sarcoma affecting the long bones, is so important that I reproduce it entire.

FORM OF SARCOMA.	INFECTED NEIGH- BORING SOFT PARTS.	INFECTED LYMPHATIC GLANDS.	RECURRED LOCALLY AFTER REMOVAL.	INFECTED THE SYSTEM GENERALLY.
	Per cent.	Per cent.	Per cent.	Per cent.
PERIOSTEAL:				
Spindle-celled	44	0	60	100
Round-celled	50	7.69	50	100
Ossifying	40	6.25	41	65.62
CENTRAL:				
Round-celled	66	8.33	25	33.33
Spindle-celled	18	0	20	23.07
Myeloid	12	0	8	22.72

When the internal organs become affected, the secondary growths will generally be found in the lung, and sometimes also in the liver and other viscera. The secondary tumors, as a rule, reproduce the special features of the primary, such as ossification, calcification, development of cartilage, etc. (Fig. 517).

In **Central Sarcoma of Bone** the tumor springs from the cancellous tissue or medullary canal. It is usually situated at or about the articular ends, expanding the bone, until in many cases a thin shell only is left surrounding the mass. The symptoms may at first closely resemble those of chronic

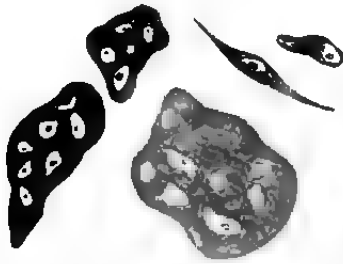

Fig. 518.—Myeloid Plates or Giant-cells from a Tumor of the Lower End of the Femur.

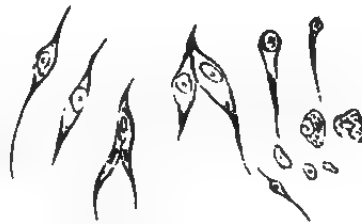

Fig. 519.—Fusiform and Oat-shaped Cells from Myeloid Tumor.

periostitis and osteitis, or abscess of bone, the only means of diagnosis sometimes being the application of a trephine. In most cases, however, the pain is not so severe as in chronic inflammatory affections. It has been pointed out by Richet, and I have often had occasion to verify the fact, that, though the articular end of the bone may have been completely destroyed by the tumor, the cartilage of the neighboring joint never becomes implicated. In these cases the close proximity of the tumor to the joint may lead to the disease being mistaken for white swelling of the articulation, as I have more than once seen happen in myeloid sarcoma of the lower end of the femur. The cartilage, however, being undestroyed, there is in these cases usually a

considerably greater degree of movement than is possible in white swelling. Central sarcoma, so long as the disease is confined within the walls of bone, develops but slowly and shows but little tendency to infect the system, but when once it extends beyond and implicates the soft parts, the danger becomes greatly increased. Spontaneous fracture is not uncommon. Central sarcomata are of four kinds: myeloid or giant-celled, spindle-celled, round-celled, and mixed spindle- and round-celled. These are further modified

Fig 520.—Calcified Nodule of Sarcoma of the Lung, secondary to a similar growth in a long Bone (188 diam.). A. Decalcified. The flat, gray surface represents the Calcified Stroma. B. Not decalcified. Shows the glistening bars of Calcified Stroma passing between the granular cells, which in some parts also are calcified.

by the formation of cysts, calcification, ossification, and the development of cartilage. Eighty-one cases collected by Butlin showed the following structure: round-celled 22, of which 17 were simple, 1 calcified, 3 ossifying, and 1 fibroid; spindle-celled 19, of which 15 were simple, 2 developing cartilage,

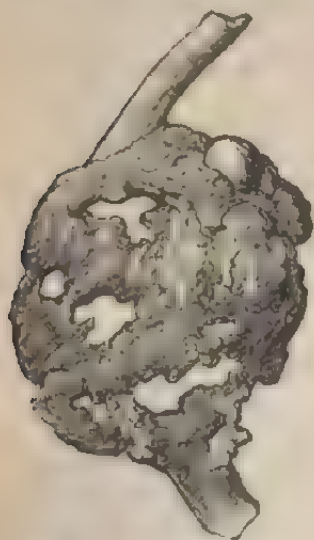

Fig 521.—Expansion of Lower End of Femur by a Myeloid Sarcoma.

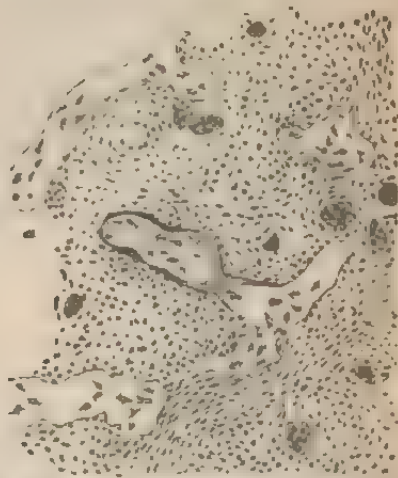

Fig 522.—Myeloid Tumor of Lower Jaw (70 diam.), showing the manner in which the bone is invaded. A. The deep surface of the section.

and 2 calcified; mixed-celled 22, of which 18 were simple, 3 ossifying, and 1 calcified; and myeloid 17, of which 14 were simple and 3 contained bony spicula. According to Gross, if the long bones only be considered, myeloid tumors form a much larger proportion than in Butlin's table.

All the central sarcomata, except the myeloid, tend to diffuse themselves widely through the medullary canal; the myeloid tumor often remains remarkably sharply limited to the articular end of the bone in which it commenced. As a central sarcoma grows, the bone becomes "expanded" by it into a mere shell, often deficient in parts, is left. If the tumor be very soft or contain cysts, this may in parts give the sensation of "egg-shell cracking."

In *peripheral, or periosteal sarcoma*, there is no expansion of bone. The tumor is from the first elastic and fixed, commencing usually at one side, but often at a later period embracing the whole bone. The forms of sarcoma met with in 80 examples collected by Butlin were the following: Round-celled 30, of which 22 were simple, 6 ossifying, and 2 developing into cartilage; spindle-celled 22, of which 13 were simple, 3 ossifying, and 6 developing into cartilage, which in some cases were subsequently becoming ossified or calcified; mixed round- and spindle-celled 28, of which 11 were simple, 6 ossifying, 5 calcifying, and 6 developing cartilage. When the

Fig. 324.—Peripheral Spindle celled Sarcoma of Shaft of Femur, successfully Amputated at Hip joint.

tumor ossifies or calcifies, it does not penetrate deeply into the compact tissue; when these changes do not take place, the bone becomes eroded and spontaneous fracture is very likely to occur. The pain accompanying a periosteal tumor is usually less severe than that of a central sarcoma. The tumor varies in consistence according to its nature from firm and elastic to semi-fluctuating. In some cases pulsation of a thrilling kind, with or without a bruit, is distinctly perceptible, especially in an advanced stage of the disease, when the vascularity of the tumor is greatly increased. Cysts are not uncommon in the softer forms of sarcoma.

STRUCTURAL CHANGES IN BONE.

Diagnosis—Central sarcoma of bone in its early stages so closely resembles *osteomyelitis* and *periostitis* that it is frequently impossible to come to a correct conclusion as to the nature of the case without cutting down on the bone and applying the trephine. In the later stages the diagnosis becomes more easy; the great enlargement of the bone, the occurrence of "egg-shell crackling" on pressure, and more especially pulsation when it is present, making the nature of the case clear.

From *cystic tumors of bone* the diagnosis is often impossible, as the great majority of cysts of bone "except in the jaws" are really soft sarcomata with cysts developed in the tumor. It is only by cutting into the diseased part that the nature of the disease can be ascertained. From *disease of the neighboring joint*, the diagnosis is made by observing that the joint does not form the centre of the swelling, and that movement, although limited, is not painful.

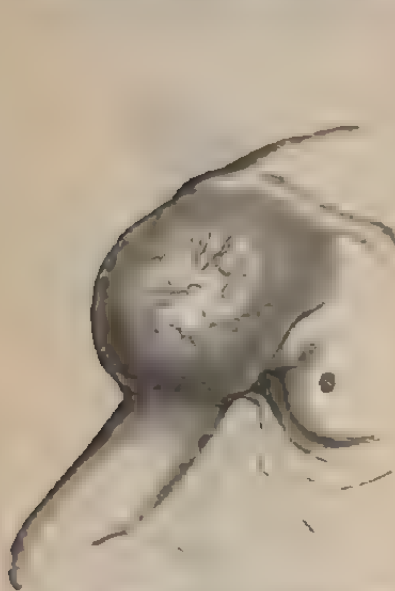

Fig. 525.—Rapidly growing malignant Tumor of the Head of the Humerus, with Spontaneous Fracture of the Shaft.

Fig. 526.—Section of rapidly growing malignant Tumor of Head of Humerus, upper end and Head of Humerus destroyed, but Cartilage of Incrustation unaffected. Tumor divided by white vertical lines—the Periosteum inside which only were the Tumor's Spectra found.

and is unaccompanied by grating or crackling in the articulation. Should the tumor have penetrated the joint, which is very rare, the difficulty of diagnosis becomes greatly increased.

Peripheral sarcoma is most frequently mistaken for a deep-seated *chronic abscess*, but the absence of true fluctuation, the presence of a rounded edge to the tumor, and its fixed attachment to the bone will usually enable the Surgeon to recognize the nature of the disease. In all doubtful cases the swelling must be punctured with an aspirator. Even when the presence of a tumor is evident, it is not always easy to make sure that it is attached to

the bone. Examination under chloroform, with complete relaxation of the muscles, will usually, however, overcome this difficulty.

The diagnosis from *aneurism* is necessarily unattended by any difficulty so long as its sac is pervious to fluid blood, and presents the characters that are met with in this condition. But if the sac have become consolidated by the deposit of stratified laminae, and thus have assumed the characters of a solid tumor, it may readily enough be mistaken for a tumor springing from the osseous structure, and amputation has occasionally been performed on this supposition (as in Fig. 417). Pulsating sarcoma may be mistaken for *aneurism by anastomosis*. In such cases, however, the history of the progress of the disease will do more to elucidate its true nature than anything else.

Having ascertained the presence of a tumor, it remains to determine the nature of the growth. In many cases this cannot be done. If the tumor is of slow growth, very firm, of considerable size, lobulated on the surface, very clearly defined, and immovably fixed to the bone, it may be a simple enchondroma. If, with the same symptoms, however, it is of more rapid growth, it may be a sarcoma developing into cartilage. The distinction is very important if it can be made, for a simple chondroma is an innocent tumor, and the surgeon in removing it may carry his knife close to the growth, but a chondro-sarcoma is usually very malignant, and amputation must be done high above it. Unfortunately the distinction is often impossible. When the tumor is central and situated at an articular end of a long bone, especially the upper end of the tibia, the lower end of the femur, the upper end of the humerus or the lower end of the ulna, or on the lower jaw, the chances are greatly in favor of its being a myeloid or giant-celled sarcoma. According to *Croft*, nearly 70 per cent. of the central tumors of the long bones are of this nature. Myeloid tumors are often somewhat globular in form, and cysts are very common in them. They commonly occur between 25 and 35, and grow slowly without affecting the constitution. When the central tumor affects the shaft of a bone it is probably one of the more malignant sarcomata, either round-celled, spindle-celled or mixed, myeloid being very rare in this situation.

The peripheral sarcomata cannot be clearly distinguished from each other. Myeloid never commences superficially, and may therefore be excluded. If the lymphatic glands are affected, it is most probably a round-celled sarcoma, the spindle-celled form very rarely spreading in this way. All forms of peripheral sarcoma may equally implicate the surrounding soft parts.

In distinguishing between the benign and malignant tumors, *Paget* directs attention to the following points. 1. The age of the patient. If below puberty or past middle life the tumor is probably malignant, unless it be a common osteoma. 2. The age of the tumor. If of more than two years' duration, it is probably not malignant. 3. If a tumor of bone have doubled its size in six months, not being inflamed, it is probably malignant.

Treatment.—Tumors of bone are necessarily beyond the reach of constitutional or local resolvents. Surgeons are consequently obliged to resort to operative interference. If the tumor be simple, it may be possible to remove in some cases by gouging or cutting it out, but if it be one of the malignant sarcomata, the only safe course consists in removing the whole bone from which it springs. If from the localized nature of the growth, its origin at an articular end of a bone, and its central position, there is reason to believe that it is a myeloid or giant-celled sarcoma, it may be sufficient to remove the part of the bone only from which it grows. In the leg this necessitates amputation, but in the lower end of the radius it is sometimes possible to excise the affected part of the bone without removing the limb. In tumors of the lower jaw it is seldom necessary to remove more than half

the bone at most. If part of the bone only be removed, the sawn surface and medullary canal must be carefully examined, and if it does not appear healthy more must be cut away.

If the tumor be peripheral, or if it be a central sarcoma of any kind other than myeloid, no means avail except the complete removal of the diseased bone. These operations are, however, not very promising, as there are few forms of malignant tumor in which the disease returns more rapidly in a secondary manner than in that of the bones. The rapidity of recurrence will, however, greatly depend upon the form of the disease, on the time when amputation is performed, and on the part where it is practised. Amputation should always, if possible, be performed in the earliest stage of the disease, before general infection has set in. If the glands be enlarged and cachexy be already present, little can be expected in the way of ultimate cure, yet I have known cases in which, even in these unfavorable circumstances, the patients have made a good recovery, life having been prolonged for months.

The selection of the line at which amputation should be performed is of great importance, and the result will materially depend upon the judgment displayed in this. If the limb be removed in the continuity of the diseased bone, there must necessarily be a great probability of a very rapid return of the growth in the stump; and this probability amounts to a certainty in those cases in which the disease being central, the whole of the medullary canal and cancellous structure are infiltrated by the tumor. In cases of peripheral disease, this return in the same bone may not take place; indeed, I have seen one case of the kind in which the disease afflicted the lower end of the tibia, and that bone was amputated in its upper third; in this case, after a lapse of some months, total recurrence of the disease took place in the pelvic bones, but not in the stump. As, however, the peripheral is more rare than the central form of the disease, and as there are no means of ascertaining the precise kind before removal, the rule, I think, should be definite to amputate at or above the next joint—at the hip joint, in malignant disease of the femur; in the thigh, for that of the bones of the leg; and at the shoulder, when the upper arm is affected. When the lower part of the femur, however, is involved, amputation through the trochanters may sometimes be substituted for disarticulation at the hip joint, the latter operation being so formidable and so fatal that the Surgeon may think it advisable not to subject the patient to so serious a risk; or amputation might be performed through the trochanters, and the head of the bone then resected. In this way the severity of the operation and the extent of wound would be lessened, whilst the whole of the diseased bone would be removed. In cases of myeloid sarcoma it is not usually necessary to remove the whole bone, as the disease almost invariably begins in the articular ends, and very rarely extends far into the medullary canal.

In some forms of malignant bone disease, however, the muscles inserted into the affected bone become speedily contaminated, and this contamination may spread widely through the substance or along the sheath of any particular muscle. Hence I think the rule in these cases should be to amputate not only above the diseased bone, but, if practicable, above the origins of the muscles in the neighborhood of the disease; thus, if there be a malignant tumor of the bones of the forearm, amputation should be done not only above the elbow-joint, but above the humeral attachments of the muscles of the forearm.

The propriety of excision of some bones, as of those of the face, in this disease, must depend on whether the morbid growth is limited to the structures that can be excised. This operation can rarely be advantageously

practised in malignant tumors, there being in general too great an implication of the soft structures in the neighborhood to justify it.

SECONDARY SARCOMATA OF BONE.—All malignant sarcomata, wherever arising, when they become generalized, may form secondary growths in the bones. Thus in a case of sarcoma of the breast under my care some years ago the fatal result was due to a secondary tumor forming in the sternum. Metastatic sarcoma not unfrequently gives rise to secondary tumors in the medulla or cancellous tissue of bone.

TRUE CANCER OR CARCINOMA OF BONE is always secondary. **Scirrhus**, when it becomes generalized, not unfrequently gives rise to secondary tumors of bone. Five cases of this kind have occurred lately in University College Hospital, which are good examples of this. Four occurred after excision of the breast. In two, the secondary tumor formed in the vertebrae, in one, in the ribs, and in one, in the femur. In the fifth case, in an apparently healthy man, the upper jaw was excised by Marcus Beck for what was supposed to be a primary tumor of the outer part of the upper maxilla and the nasal bone. After death a primary scirrhus cancer of the pancreas was found, and the tumor of the jaw presented the same structure.

Epithelioma of bone rarely occurs as a secondary growth, it is usually the result of direct extension from the primary tumor.

A very rare form of malignant growth is occasionally met with in the thoracic body, which almost exactly resembles the normal gland in structure. It has a peculiar tendency to give rise to secondary tumors of the same structure in the bones. Cases of this kind have been recorded by Coburn, Morris, and others. In some cases they have pulsed strongly.

All secondary cancerous tumors of bone are central, commencing either in the medulla or cancellous tissue.

PULSATING TUMORS OF BONE.—OSTEO-ANEURISM.—Pulsating tumors of bone, or osteo-aneurisms, are a mixed group of growths possessing in common one feature, that they pulse strongly, so as in some cases almost to resemble a true aneurism. The great majority of these are soft vascular sarcomata, in which, as Billroth has pointed out, small aneurismal dilatations may exist on the vessels, which form a close network throughout the mass. *Billroth* states that pulsation was present in 20 per cent. of the myeloid tumors, 12 per cent. of the central spindle-celled growths, and 33 per cent. of the central round-celled sarcomata, of which he had collected the records. In peripheral sarcomata pulsation was very rare. It is evident that pulsation cannot be recognized in central tumors until the bony wall has been completely destroyed at one side, and it is possible that the frequency with which central tumors pulse distinctly may be due to the fact that the vascular mass of the tumor is surrounded on all sides but one by unyielding bone.

Excluding all these cases, two other kinds of pulsating tumors have been described as occurring in bone. In one of these which is very rare, there is developed in the bone a structure, which is composed of a **vascular erectile growth**, closely resembling a capillary nevus in structure, composed of an anastomosis of vessels, interlacing in every way, so as to form a soft reddish tumor (Fig. 527). In the second form a hollow cavity is formed in a bone, scooped out of the cancellous structure and filled with blood, partly liquid and partly coagulated, and having arterial branches opening into it. The shell of bone surrounding this cavity is very thin and expanded, and after a time is usually completely absorbed on one side. This constitutes the "**true aneurism of bone**." Its mode of origin is uncertain. *Volkmann* suggests that in some cases it may be a soft sarcoma, the original tissue of which has been entirely softened and broken down by hemorrhage into its substance. Such cases are extremely rare, and until some have been recorded with

accurate microscopic examination of the contained clot and the surrounding bone we must hesitate to form any opinion of their true nature.

Situation.—Pulsating sarcomata may be found anywhere, but are most common in the bones of the skull, the lower end of the tibia and upper end of the femur. Nævoid growths are most common on the skull. The "true aneurism of bone" has been said to occur most frequently in the head of the tibia.

Symptoms.—When the tumor is merely a highly vascular sarcoma the symptoms that it gives rise to are the same as have already been described, indicating a central sarcoma of bone, with the addition of pulsation and bruit. In these the pulsation is very distinct and superficial, and commonly of a thrilling character; it may be distinctly expansile in character; the bruit is usually soft and blowing, but not unfrequently harsh, loud, and whizzing. In true osteo-aneurism, according to Néaton, the bruit is often absent. In

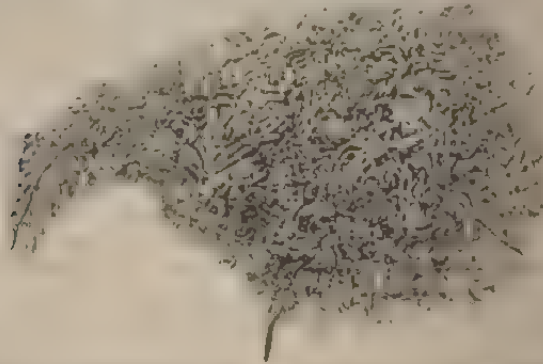

Fig. 327.—Aneurism by Anastomosis of One of the Parietal Bones.

pulsating sarcomata I have heard the bruit peculiarly loud, rough, and superficial. On compressing the main artery leading to the part of the limb in which the tumor is situated, all movement and bruit commonly cease in it, and the tumor lessens in size. By pressing upon the growth when it is thus diminished, if it be a "true aneurism of bone," it will commonly be found to have a bony margin, with a central depression. In some cases the tumor is fed by several arterial branches, which may be felt distinctly pulsating under the skin. This is more particularly the case in soft sarcomata occurring upon the bones of the pelvis and the scapula, and then the bruit and pulsation cannot be made to cease in it. All these signs are commonly somewhat intermittent, the pulsation appearing perhaps in the earlier stages of the disease, and disappearing as it advances; or the reverse may occur, the pulsation and bruit becoming distinct as the disease increases in size, and meets with more resistance in its outward growth.

Diagnosis.—It is of considerable importance to diagnose the different forms of pulsating tumor of bone from one another, as both the treatment and prognosis differ according as the disease is a "true aneurism of bone," or a pulsating sarcoma. The true osteo-aneurism is so rare that its existence is often denied, and should it be met with it will have so many signs in common with the *pulsating* sarcoma, that it will be almost impossible to effect the diagnosis. It is well to bear in mind that the malignant sarcomata are sometimes multiple, occurring, with pulsation and bruit, in more situations than one; thus I have seen growths of this kind, with their signs well marked, springing both from the pelvis and from the ribs. The true osteo-

aneurism has been described as occurring only in the articular ends of long bones; whereas the malignant disease, though commonly occurring in these situations, is also frequently found in other parts of the body. Besides these, there are two conditions which, in many cases, will enable the Surgeon to determine that the pulsating tumor is an osseous aneurism: viz., the absence of all bruit, though the pulsation be distinct, and the detection by firm pressure, after the tumor has been diminished by compressing the artery leading to it, of an osseous margin around its depressed centre.

From *ordinary aneurism* the diagnosis of pulsating tumors of bone is, in many cases, attended by almost insuperable difficulties. So great are these, that there are many cases on record in which the most experienced Surgeons have ligatured arteries for tumors that were supposed to be aneurismal, but which have turned out to be pulsating sarcomata. A principal point to be attended to in effecting the diagnosis is the situation of the tumor, which may occur away from the ordinary sites of aneurism, in parts of the body where there is no vessel large enough to give rise to such a disease—as, for instance, about the head of the fibula or the outer side of the pelvis. Then, again, its incorporation with the subjacent bone, the want of a distinctly limited and circumscribed outline, and the existence in many cases of plates of bone in the wall of the tumor—giving rise, perhaps, on pressure, to the peculiar rustling or crackling sound characteristic of central bony growths—will enable the Surgeon to come to a conclusion as to the true nature of the tumor. In this he will be further assisted by its having on compression a soft, doughy, or spongy feel, or appearing as a depression surrounded by an osseous margin. In many cases also, the less impulsive character of the beat of the tumor, the peculiar shrill and tremulous whiz in the pulsation and bruit, will throw much light on the nature of the disease. But it cannot be doubted that, when tumors of this kind occur in some of the ordinary situations of aneurism, as about the brim of the pelvis, and in the popliteal space, the diagnosis is surrounded with difficulties which no amount of surgical skill or tact may be able to overcome.

From *ordinary tumors of bone*, the existence of pulsation and bruit will always suffice to distinguish the growths under consideration.

Treatment.—Pulsating sarcomata of bone must be treated exactly in the same way as those that do not pulsate.

Ligature of the main artery has been practised in several supposed cases of “true aneurism of bone,” but in the majority of these the disease turned out to be a soft sarcoma, and consequently no benefit resulted. The growth of the tumor was not even retarded. Roux, however, has recorded a case in which he cured a pulsating swelling in the lower end of the radius by ligature of the brachial artery. Lallemand cured a so-called aneurism of bone by the same treatment. In a patient of Dupuytren's no return of the disease took place for six years, when it recurred, and amputation became necessary.

CHAPTER XLVIII.

DISEASES OF JOINTS.

THE various joints of the body may become the seat of Inflammatory Affections of an acute or chronic character; of Strumous Disease, or of various other morbid conditions, such as more or less permanent rigidity, or Ankylosis, the formation of Foreign Bodies within their cavities, and Neuralgia. In studying these various articular affections, it must be borne in mind that a joint is composed of a number of different tissues; of synovial membrane, cartilage, bone, ligament, and capsule, or investing fibrous expansion. In any one of these structures the disease may primarily begin though eventually the morbid process often spreads to other tissues besides that which was originally involved. The merit of having been the first to point out the true mode of studying these affections in reference to the different structures in which they have originated, and to have set aside that coarse pathology which, under the general terms of "arthritis" and of "white swelling," confounded together these various diseases, is certainly due to Sir Benjamin Brodie.

SYNOVITIS.

Inflammation of the Synovial Membrane, the most common perhaps of all the articular affections, may be acute, subacute, or chronic.

CAUSES.—Synovitis results usually from exposure to cold, especially in rheumatic or gouty constitutions. In these cases it commonly happens that more joints than one are implicated at the same time; and the affected articulations are more frequently those that are most exposed by having the thinnest covering of soft parts, and by being especially subjected to transitions of temperature, such as the knees and ankles. Synovitis with moderate effusion is sometimes met with in the secondary stage of syphilis at the same time as the cutaneous eruptions. Gonorrhoea is an occasional cause of inflammation of the synovial membrane and acute synovitis may occur in pyæmia and other forms of blood poisoning. Injuries of joints, as blows, bruises, wounds, or sprains, will also frequently occasion this inflammation; but when arising from such causes, it is usually associated with inflammation of the other textures of the articulation.

PATHOLOGY.—As uncomplicated acute synovitis is never fatal, we seldom have an opportunity of studying its pathology. It would, however, appear from the examination of joints in cases of synovitis from injury, as well as from the experiments of Richet, Bonnet, and others, who have induced traumatic synovitis in animals, that there is in the first instance an inflammatory congestion of the synovial membrane, with loss of its peculiar satiny polish. The synovia is then increased in quantity, and becomes thin and serous, and after a time intermixed with inflammatory exudation which is poured out with it. If the disease progress favorably, these products are more or less completely absorbed. In more rare cases, the congestion and swelling of the synovial membrane increase, until at last it becomes so turgid and distended with blood and effused fluids, that a kind of chemosis results; a thin purulent-looking fluid is poured out, composed of granular corpuscles—partly

migrated leucocytes, and partly desquamated and degenerated endothelial cells—floating in a serous liquid.

In all cases of acute synovitis the fringes of the membrane become swollen, and their vessels injected with blood, so that they form prominent red elevations, especially at the margins of the cartilages. The inflammation in such cases frequently extends to the other structures forming the joint, and the disease then forms one variety of acute arthritis. In other cases, granulations are thrown out on the looser portions of the membrane, and becoming invested with bloodvessels, constitute fringed and villous membranous expansions, lying upon the subjacent cartilage.

SYMPTOMS. Acute Synovitis.—The symptoms of synovitis consist of pain and heat and distention of the joint, with fluctuation. If it be large and exposed, the pain is severe, especially at night, being greatly increased by moving or pressing upon the articulation; it is usually sharp, but when the disease occurs in rheumatic or gouty constitutions, it is of a gnawing character. In purulent synovitis from pyæmia, it is usually very superficial, instead almost cutaneous. On laying the hand on the joint, it will be felt to be hot. The swelling of the affected joint is considerable, and evidently depends on accumulation of fluid within the synovial sac, the extreme outline of which is rendered apparent by the tension to which it is subjected. Thus in the knee it rises up high in the thigh under the vasti, to the extent of three or four inches above the upper border of the patella, the swelling being higher on the inner than the outer side of the limb, whilst in the elbow it rises in the same manner under the tendon of the triceps. There is but little, if any, effusion into the surrounding tissues: and hence the outline of the joint can be distinctly felt, and fluctuation perceived in it. The limb is usually semi-flexed, for in this position there is the greatest general relaxation of the ligaments, and it consequently gives the patient most ease. The joint cannot be moved without considerable pain. The constitutional febrile disturbance is tolerably severe, especially if the affection occur in a rheumatic constitution.

Chronic Synovitis.—The disease, at first acute, may terminate in a sub-acute or chronic form; or, subacute at its commencement, it may fall into a chronic condition. Chronic synovitis is characterized by all the symptoms of the acute variety of the disease, but in a less severe degree. The swelling and weakness of the joint are the most conspicuous local conditions. In some cases, the swelling from accumulated serous fluid is so considerable as to constitute a true dropy of the joint—**Hydrarthrosis**. This accumulation of fluid, partaking in various degrees of the characters of serum and synovia, is usually preceded or accompanied by evidence of synovial inflammation: but, though this generally happens, it is not invariably the case. Richet, in particular, has recorded instances from which it would appear that inflammation is not a necessary or invariable accompaniment of the affection, the synovial membrane being, indeed, preternaturally white, and looking as if it had been washed or soddened; and though these cases are rare, those that occasionally present themselves to the Surgeon bring of a decidedly inflammatory character, yet their occasional occurrence is sufficient to establish the existence of a passive, as well as of an inflammatory form of the disease.

The presence of an abnormal quantity of fluid in the joint is always indicated by fluctuation and undulation and by the peculiar shape acquired by the part. Thus in the knee, which is the most common seat of the affection, the patella will float, as it were, on the fluid. If the distention be not too great, by placing the finger on the knee-cap and pushing it sharply towards the tænar it can be felt to sink through the fluid and strike on the bone beneath. This sign is of great importance, as it enables us to distinguish

between simple synovitis with effusion and distention of the joint by soft granulation-tissue in the early stages of white swelling. In order to elicit it the patient must be lying down with the muscles of the thigh perfectly relaxed. All the natural hollows about the knee are obliterated; the distended pouches of the synovial membrane project distinctly on each side above the patella, and the hollow on each side of the ligamentum patellæ is obliterated by the infrapatellar fat which is pushed downwards by the pressure of the fluid in the joint. In the elbow there is a soft and fluctuating swelling on each side of the olecranon, extending above it on each side of the tendon of the triceps, which forms a depression in the middle line; and in the shoulder there is a general roundness and distention of the articulation. It is said that, in some cases, the distention of the joint has been so great that the synovial membrane has been ruptured, and the fluid poured forth into the surrounding areolar tissue. In these cases, however, it is probable that some destructive change in the synovial membrane preceded its rupture. In more chronic cases the ligaments may become relaxed, and spontaneous dislocation may take place (vol. i. p. 625).

In some cases of chronic synovitis distinct *crackling* will be felt in the interior of the joint, on laying the hand over the articulation whilst it is freely moved. This appears to me to be due to the existence of bands of fibrinous exudation in the interior of the joint, through which the fluid is pressed by the articular movements, and thus occasions the sensation which is met with under similar circumstances in enlargements of the bursæ, and in fluid effusions in the sheaths of tendons.

TERMINATIONS.—The termination of synovitis will depend mainly on its cause. When simple and uncomplicated, arising as the result, perhaps, of rheumatic influences, it will in most cases terminate in complete resolution. In other instances, however, as a consequence of inflammatory exudation, warty vegetations or concretions may form within the joint, or bands stretching across its interior or incorporated with its capsule, may occasion more or less permanent stiffness. Septic synovitis following a wound generally goes on to suppuration within the joint with erosion or disintegration of the cartilage, and eventually to complete disorganization of the interior of the articulation. The same happens in the puerperal and pyæmic inflammations of joints; in which cases the morbid process commencing in the synovial membrane extends to the cartilages, eventually destroying them.

The chronic or subacute synovitis and hydrarthrosis usually terminate favorably, although the joint is generally left in a weak, relaxed condition, from which it may not recover for many months; but occasionally, more particularly in strumous constitutions, the disease runs on to suppurative destruction of the joint. This, however, is rare; yet its occurrence, in some instances, should make the Surgeon careful not to confound the fluctuation of serous accumulation with that of a purulent collection. In the latter instances, the symptoms of acute inflammation will always have preceded.

TREATMENT.—The treatment of synovitis depends partly on the severity of the symptoms, and partly on the cause of the disease. If a joint have been injured subcutaneously, and synovitis be apprehended, or, indeed, have commenced, no treatment will be found more efficacious than the continued application of ice in India-rubber bags of sufficient size to envelop the whole of the joint. In this way the inflammation may often be checked or completely arrested, the joint being, of course, kept at the same time perfectly at rest on a splint or in a sling. Should the disease have made progress, and should the ice fail in arresting it, then, if the patient be young and strong, the free and repeated application of leeches to the inflamed articula-

tion, followed by fomentations and accompanied by perfect rest of the part on a splint, or on pillows properly arranged, will be the most useful treatment. At the same time, saline purgatives with antimony must be given, and the patient kept on a low diet. The treatment of synovitis following open wounds has been fully described in the chapter on Wounds of Joints.

If the disease be *rheumatic*, leeches may be applied, followed by hot fomentations, and rest of the part in the elevated position; at the same time salicylate of soda may be given in ten-grain doses if there be much febrile disturbance, and Dover's powder should be administered if there be much pain at night. In some instances great benefit will result from the administration of Dover's powder and calomel, in small but frequent doses. If the patient be gouty, colchicum should be given. When the disease is of *syphilitic* origin, the application of blisters, followed by calomel and opium, will be attended with marked success.

When the synovitis is *subacute* or *chronic*, the same principles of treatment must be adopted, modified according to the intensity of the affection. In these forms of the disease, rest is perhaps the most important element in the treatment, everything else proving nugatory unless this be attended to; the limb is usually best fixed by leather splints, buckled on so that they may be removed in order to make the necessary applications to it. In these cases, repeated blisterings over the whole of the joint constitute, perhaps, the most useful local means that we possess. In a more advanced stage, counter-irritation by means of stimulating embrocations, together with douches, either of warm sea-water or of some of the sulphurous springs, such as those of Aix or Buzançon, will prove most useful; and when all inflammation has been subdued, and weakness of the joint merely is left, the joint should be properly strapped with soap-plaster, spread upon leather. Amongst the internal remedies likely to be of most service, may be mentioned the iodide of potassium, either alone or in some bitter infusion.

In *hydrarthrosis*, rest and repeated blistering will usually promote the removal of the fluid. In addition to this, the employment of pressure, either by means of strapping or Martin's India-rubber bandage, and friction, with absorbent remedies, as the iodine or mercurial ointment or oleate of mercury combined with the internal administration of iodide of potassium or with a mild mercurial course, will often procure the absorption of the fluid. If these means fail, the aspirator may be used to empty the joint of its fluid, the puncture being closed with collodion, and in extreme cases we have a very powerful method of cure at our command in the injection of the joint with tincture of iodine. This plan, a sufficiently bold one, has been much employed by Jobert, Velpeau, and Bonnet. These Surgeons used the tincture diluted with two or three parts of water. A small trocar is introduced into the joint, a moderate quantity of the serous fluid is let out, but not all, and then a corresponding quantity of the iodine solution is thrown in; and after being left for a few minutes, is allowed to escape. Inflammation of the joint, which is a necessary result of this procedure, comes on. This is treated by ordinary antiphlogistic means, and, according to the statements of the French Surgeons, has in no case been followed by any serious consequences, but in several instances a complete cure without ankylosis has resulted; a new and healthy action having been imprinted on the synovial membrane. This mode of treatment does not appear hitherto to have met with much support in this country; yet it certainly deserves a trial, though recourse should not lightly be had to it, as it is evident that the induced inflammation might exceed the expected limits. In one case of hydrarthrosis of the knee, in an old man, in which I employed it, about six ounces of thin synovia were drawn off, and a drachm of strong tincture of iodine was injected into the

joint. Slight inflammation only ensued; and the disease, which was of two years' standing, was completely cured. The chief points that appear to require attention are that no inflammation be going on at the time, there being no tenderness or pain in moving the joint, the effusion being quite passive, and of a very chronic character; and, above all, that no air be allowed to enter with the injected fluid. If other methods of treatment fail, the joint may be drained by means of an India-rubber tube inserted with all antiseptic precautions. It may be retained for ten days or a fortnight, the dressing throughout being strictly antiseptic. The carbolic gauze dressing will be found the safest in these cases. After drainage of the joint has been removed, the articulation is usually left weak for some length of time, in consequence of the stretching to which its ligaments have been subjected; here cold douches and an elastic bandage will constitute the best mode of treatment.

ACUTE ARTHRITIS.

By *Acute Arthritis* is meant an acute inflammation affecting the synovial membrane and rapidly extending from it to the other structures that enter into the formation of a joint. The disease may arise primarily in the synovial membrane, or the affection of the synovial membrane may be secondary to disease beginning in the bones or in the soft parts around the joint. In the latter case, the symptoms characteristic of acute arthritis do not set in until the mischief has extended to the cavity of the joint. In some forms of acute arthritis the symptoms clearly indicate that the inflammation of the synovial membrane precedes that of the ligaments, while in others the extension is so rapid that all the structures of the joint may seem to be affected simultaneously.

It will be most convenient to describe first the symptoms and pathological changes which are characteristic of acute arthritis from whatever cause it may arise, and afterwards to point out the modifications of the process dependent upon its mode of origin.

Symptoms.—The symptoms of acute arthritis that are most marked are the pain, heat, swelling, and peculiar position of the joint. The *pain* is often severe, tense, and throbbing; so acute is it sometimes, that the patient screams with agony; he cannot bear the bed to be touched, the room to be shaken, or the slightest movement communicated to the limb, any attempt at examination of the joint in such cases being attended with insupportable agony. There are usually nocturnal exacerbations, and the pain is commonly referred with especial severity to one particular spot in the joint, thus it is generally felt at the inner or under side of the knee-joint, and at the outer aspect of the hip. The *heat* of the diseased joint is considerable, and is often accompanied with more or less superficial redness. The *swelling* is uniform, involving the whole of the articulation, and not projecting at certain parts of it, as when the synovial membrane alone is affected; it is generally not very considerable, and has a soft and doughy, rather than a fluctuating feel. The *position* of the affected limb is peculiar, and that attitude is involuntarily adopted in which the patient will have the greatest amount of ease, thus, if the knee is affected, it is semiflexed, and the limb is rotated outwards, if the hip, the joint is flexed and the limb abducted and rotated outwards with the knee semiflexed, if the elbow, it is bent. *Spasms or startings* of the limb, often of a very sharp and painful character come on at times; more particularly at night. Amongst the most distressing symptoms in the more advanced stages of acute disorganization of a joint are the painful startings of the limb whenever the patient falls asleep. The

muscles becoming relaxed the softened ligaments allow the joint to become slightly displaced; a reflex contraction of the muscles immediately takes place, and the patient wakes with a painful spasmodic jerk of the limb, inducing a feeling of alarm, that is often very distressing. The constitutional disturbance is very severe, and of an actively febrile type.

Having reached this stage, in some cases the symptoms gradually subside, the heat lessens, the pain loses its acute character, the swelling slowly diminishes, and recovery takes place after many weeks or months, the joint being left permanently stiffened from contraction of the inflamed ligaments, or sometimes firmly ankylosed, the articular surfaces being united by dense fibrous tissue or bone, according as the cartilages have been partially or completely destroyed during the acute stage.

More commonly as the disease progresses, *suppuration* takes place within the joint, which becomes hot and red, with a good deal of throbbing pain, the skin covering it is oedematous, and at last fluctuation is perceived where the coverings are thinned. In some cases the suppuration occurs with very great rapidity, and luxation of the head of the bone takes place. In other cases the synovial membrane and capsule of the joint give way without any loosening of ligaments or displacement of bones, pus becomes infiltrated into the areolar tissue around the joint, an abscess forms external to the articulation, and extensive purulent collections become diffused through the limb. As the joint becomes loosened by the destruction of its ligaments, the bones become mobile, and grate against one another where the incrusting cartilage has been removed, thus giving rise to very severe suffering. The cartilages may, however, in some cases be very extensively destroyed, and yet no grating take place; this is owing either to the destructive action being limited to the edge of the incrusting cartilage, the opposed surfaces being sound, or else to the interior of the articulation being filled up with granulation-tissue after the removal of the cartilages. But though abscess, either within the joint or external to it, usually forms when the bones grate and the cartilage disintegrates, yet it occasionally happens that these conditions exist—the symptoms indicative of erosion of cartilage, such as painful startings of the limb, grating, and preternatural mobility of the joint, being present—and yet no abscess forms; all the symptoms subside under proper treatment, and the joint recovering, though with a certain degree of ankylosis. But the reverse also may occur. Suppuration may take place in a joint, the synovial membrane and the capsule may give way, extensive infiltration of pus into the deep areolar planes of the limb may occur, and yet no laxity of ligament, no preternatural mobility of the bones, no grating of the articular surface, indicate the disorganization of the articulation which is in progress. This condition may occur in any joint, I have most frequently met with it in the knee. There the upper and usually the outer part of the capsule generally gives way, and the pus diffuses itself deeply beneath the extensor muscles of the thigh, sometimes even between the periosteum and the bone. In these cases the thigh swells greatly, the limb becomes oedematous, and a deep and obscure sensation of fluctuation may perhaps be felt, more especially towards the outer and lower part of the limb just above the knee. The swelling of the joint has perhaps subsided on the escape of the pus from the cavity, giving a false idea of security, which is confirmed by the absence of signs indicative of disorganization, such as lateral mobility and grating. But on pressing the thigh downwards, the joint will be found to feel the patch will float again, and there is an evident communication between the interior of the synovial membrane and the extensive diffused abscess in the thigh. In cases of this kind the pus will first come to the surface about two or three inches above and to the outer side of the joint;

and, on a free incision being made here, immense quantities may be let out. In these cases fluctuation is often masked by the oedema of the limb, and by the thickness of the overlying mass of areolar tissue and muscle, and will require the closest examination and the most practised hand for its detection. After suppuration has taken place, the constitutional disturbance partakes of the irritative type, the patient suffering severe pain, and being worn out by want of rest. After the abscess is opened, unless special means are taken by drainage and antiseptics to prevent the accumulation of decomposing discharges in the articular cavity, septic poisoning or pyæmia is very likely to follow; or hectic leading to death from exhaustion and irritation may occur, unless the diseased part be removed. In other and less severe cases it falls into a state of chronic thickening, perhaps with fistulous openings leading down to the diseased structures; and in some of the more favorable instances the patient may recover, with a permanently rigid joint.

The *muscles* in the neighborhood of an inflamed joint undergo a species of acute atrophy. The wasting and the flaccidity are both more than can be accounted for by simple disuse.

In some cases the muscular changes are more than atrophic, and *redex paralysis of the muscles of a limb*, consequent upon inflammation of a joint, is occasionally met with. I have seen this singular affection in the extensor muscles of the thigh and in the muscles of the scapula, in cases of acute arthritis. In these cases the affected muscles rapidly waste. The wasting is not due to disuse alone, for it affects certain groups of muscles only, others which are equally inactive not being atrophied. But not only do certain groups of muscles in the affected limb become wasted, as for instance the extensors of the thigh or those passing from the scapula to the humerus, whilst the other muscular structures of the limb preserve their normal conditions, another change takes place in them. They lose their electric irritability, and, in fact, become perfectly paralyzed. In the lower extremity the leg cannot be extended, in the upper the arm cannot be raised. This condition is extremely chronic. It will last for many months after the joint-affection, from which it starts, has been cured, and may lead to permanent atrophy of the paralyzed muscles. The treatment consists in stimulation of the affected muscles, by sea-baths, electricity, and friction, combined with methodical movements of the limb. Strychnine may be given with advantage when the lower limbs are affected. I have seen this redex arthritic paralysis chiefly in persons suffering from spinal exhaustion, in neurotic women, and in men addicted to sexual excesses.

Diagnosis—*Abscess* may form external to, but in immediate contact with the capsule of a joint, and closely simulate disease of the articulation. In these cases the absence of serious constitutional disturbance, the irregularity of the swelling, greater on one side than the other, its extension over bony points, as the patella or olecranon, the superficial character of the fluctuation, the absence of all rigidity about the joint or of that preternatural mobility in a horizontal direction which arises from softening of the ligaments, and of other severe local symptoms, such as pain, starting, looseness, or grating, will enable the Surgeon to elicit a correct diagnosis.

PATHOLOGY—It is very rarely that the opportunity arises of examining a joint affected with acute arthritis before it has reached the stage of suppuration. In that stage all the component parts of the joint will be found to present marked changes, varying somewhat with the cause and the degree of acuteness of the inflammatory process. The following may be taken as the appearances in a typical case.

The *synovial membrane* is thickened and intensely injected; if the disease has advanced beyond the earliest stage, this membrane is no longer recognizable as such, being converted into a layer of granulation-tissue, the site of the

tridges being marked by fleshy vascular projections of the same tissue. The granulations are seldom healthy; most commonly they present the same appearance as those on the surface of an inflamed ulcer of the leg, being covered by a dirty yellowish layer composed of degenerated granulation-cells held together by coagulated inflammatory exudation. If the joint have been opened, and decomposition of the discharges has taken place, the diseased synovial membrane may be covered by opaque membranous patches almost resembling a diphtheritic membrane. In the later stages of arthritis, the granulations covering the opposed surfaces of any pouches of the synovial membrane will be found to have coalesced, the cavity of the joint being in this way to a great extent obliterated.

Microscopic examination of the diseased membrane shows only the ordinary appearances of inflammation. The endothelial cells covering the membrane have disappeared, the fibrous layer is first infiltrated with new cells, before which the original tissue more or less completely disappears. In the layer of round cells thus formed, new vessels are developed, and granulation-tissue is thus produced.

The contents of the synovial cavity are in the very earliest stages composed of thin pus mixed with synovia, but as the membrane very soon ceases to yield its normal secretion, the fluid assumes the character of ordinary pus. In cases in which the disease stops short of suppuration, an abundant coagulable fibrinous exudation is said to have been observed.

The ligaments are early affected by extension of the inflammation to them from the synovial membrane. The bundles of fibres are at first separated from each other by a coagulable inflammatory exudation, and the ligaments thus become swollen, and present at first a waxy or semigelatinous appearance. As the disease progresses the fibres become softened, and the ligaments yield, allowing the osseous surfaces to be displaced by the tonic contraction of the muscles, or the weight of the limb. The inflammation extends from the ligaments to the *periosteum of the articular ends of the bones* entering into the joint. The periostitis thus set up usually assumes the osteoplastic form (p. 274), and irregular masses of new bone, often arranged in jagged spur-like processes, are formed in the neighborhood of the articulation. This is more marked in the less acute forms of the disease, or when, after the escape of pus from the joint, the process has become chronic.

The soft parts in contact with the ligaments are oedematous in the early stages, but subsequently as the disease advances, they may become fused with the capsule of the joint, so that it is impossible accurately to separate them. Abscesses not unfrequently form outside the joint, having no direct communication with its cavity.

The cartilages covering the articular ends of the bones in all cases present most important changes. These are never primary: in every case it will be found that the morbid process proceeds either from the articular surface, or from the bone beneath. When the latter is the case, the affection of the cartilage is antecedent to the acute arthritis; this condition commencing when the cartilage is perforated, and the joint becomes infected by the products of the disease which has commenced in the bone.

When the cartilage is affected in consequence of acute suppurative inflammation of the joint, the first change observed is a loss of its natural smoothness and polish. Its bluish-white tint becomes more opaque, and often assumes a slightly yellowish tinge. This is followed by loss of substance in those parts at which the opposed articular surfaces are in contact in the latest position assumed by the inflamed joint. Finally the cartilage is completely destroyed at these parts, and the cancellous tissue of the head of the bone is exposed. As soon as perforation takes place, the suppuration extends between the cartilage and the bone, the pus being formed from the

vascular medullary tissue of the cancellous spaces. The cartilage thus becomes loosened, and is bathed by pus on each side. Its nutrition being cut off it perishes, becomes yellow in color, and tough and leathery in consistence. Microscopic examination shows that the process is one of sloughing and disintegration. The matrix is opaque and granular, and the cells show no signs of proliferation, but on the contrary have broken down into a mass of fat granules.

At the margins of the cartilages in those parts not exposed to pressure, and in those cases of acute arthritis which terminate without suppuration, the destruction of the cartilages takes place by a process of true ulceration. The cartilages are overlapped at their margins by the granulation-tissue formed from the inflamed synovial membrane. On removing this the surface of the cartilage will be seen to be marked by irregular hollows filled with a similar tissue, and in a later stage the cartilaginous tissue will be found to have been destroyed to a greater or less extent. In other parts of the cartilage similar changes may be observed, but they are always most marked in the neighborhood of the vascular fringes of the synovial membrane. So much is the case that Aston Key was led to believe that the destruction of the cartilage was directly effected by the development of a fibrinated or fringed vascular network or tissue from the synovial membrane, by which the process of absorption was carried out. The true nature of the changes occurring in ulceration of cartilage was first described by Goodsir, and his observations were confirmed and extended subsequently by Keftren and Rainey, who pointed out the fact that cartilage, like other extravascular tissues, may undergo changes independent of the protrusion of vessels into it. If a vertical section be made of a piece of articular cartilage in process of ulceration, the changes observed will vary with the acuteness of the process. In some cases the appearances will closely resemble those already described as being met with in ulceration of bone. The surface of the cartilage is seen to be irregularly hollowed out, the hollows being filled with small round cells, having the ordinary appearance of the migrating leucocytes observed in acute inflammations elsewhere; immediately beneath these, the matrix of the unaltered cartilage is cloudy, and the cartilage-cells may be granular, but there is no evidence of proliferation. There is, in fact, nothing to prove that the new cells are derived from the pre-existing cells of the cartilage, and that the process is not exactly analogous to the destruction of bone by cells derived from the vascular medullary tissue, probably by migration from its vessels.

In less acute processes, on the other hand, the destruction of the cartilage is undoubtedly due to changes commencing in its own cells. In a vertical section proceeding from the healthy cartilage to the diseased surface the following appearances are observed. In from the fifth to the twelfth layer from the surface the cells are seen to be undergoing proliferation; in each capsule two to four cells are found; proceeding towards the diseased surface, the number of cells in each space increases, and they gradually lose the characteristic appearance of cartilage cells and become indistinguishable from the round cells of granulation-tissue. As the cells multiply the space containing them necessarily increases at the expense of the surrounding matrix, and at the same time the capsule becomes more and more indistinct and at last disappears altogether. The matrix near the surface becomes cloudy and granular, and at last completely disappears before the enlarging cell-spaces, which then coalesce, and thus there is formed on the surface a layer composed entirely of small round cells identical in appearance with those of ordinary granulation-tissue. The homogeneous intercellular substance may then soften and the cells may be cast off into the joint as pus cells, or

should the disease tend towards recovery new vessels may penetrate the granules of cells proceeding from the nearest vascular tissue, and thus a vascular granulation-tissue may be formed, which will take part in the process of repair to be subsequently described.

In order to distinguish these three processes from each other, we may term the first, *resorption with disintegration*, the second, *ulceration without proliferation*, and the third, *ulceration with proliferation*.

The *bones*, when exposed by destruction of the cartilages, become affected more or less deeply by the inflammatory process. The changes that occur need no description, as they are identical with those already described in the chapter on Inflammatory Processes in Bone. They usually assume the form of *infective osteitis with suppuration*, or simple *caries*, but if the process be very acute, the inflammatory products in the cancellous spaces may break down into pus before the bony trabeculae have been completely absorbed, and thus portions of the cancellous bone may be cut off from their nutrition and perish forming sequestra (caries necrotica). In other cases the inflammation in the cancellous spaces may spread rapidly, and diffuse osteomyelitis be set up. This is especially prone to happen when the original inflammation in the joint is septic or infective in character.

CAUSES AND VARIETIES OF ACUTE ARTHRITIS.—Acute arthritis arises from many different causes, and the course of the disease varies somewhat according to its mode of origin. The following are the chief forms of the disease met with in practice.

Acute Traumatic Arthritis, or Septic Arthritis.—This arises as a consequence of a penetrating wound of a joint, with admission of impure air and subsequent decomposition of the discharges. It rapidly terminates in suppuration, and in many cases leads to complete destruction of the articulation. It has been already fully described with Injuries of Joints vol. i, p. 480.

Acute Infective Arthritis.—Acute inflammation of one or more joints is a common local effect of more than one general infective process. It is met with in pyæmia arising from wounds, in puerperal fever, scarlet fever, smallpox, and sometimes after typhoid fever. These are probably closely allied if not identical conditions, the general infection taking place from the placental surface in puerperal fever from the ulcerated throat in scarlet fever, from the pustules of smallpox, and from the ulcers in the intestines in typhoid fever, just as, in ordinary pyæmia, it takes place from the unhealthy wound. Puerile arthritis begins suddenly, with very acute superficial pain. It differs from many other forms of acute arthritis in the rapid admission into the joint which occurs at the commencement of the attack. It thus resembles simple acute synovitis in giving rise to a swelling, which at first assumes the outline of the distended synovial membrane.

If the patient die at this stage, the joint will be found to have undergone but little change, the synovial membrane is injected, and the fringes swollen,

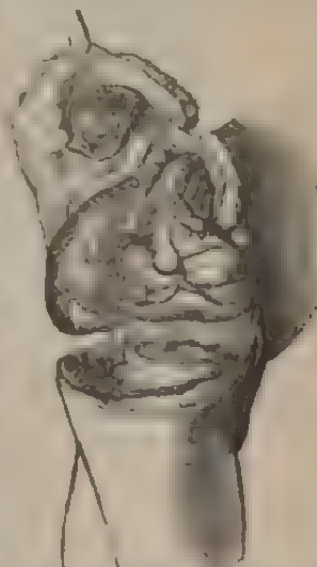

Fig. 578.—Interior of knee disorganised by Acute Pyæmic Inflammation.

and the cavity of the articulation contains a quantity of thin pus mixed with synovia. If the patient survive, however, more than a few days after the joint has become affected, the inflammation extends to the ligaments, destruction of the cartilages commences, and the case then runs the ordinary course of acute arthritis. It is sometimes possible to arrest the progress of the inflammation before the destructive changes set in, by early opening, free drainage, and antiseptic treatment, but even then considerable thickening and contraction of the capsule usually results, leaving the joint more or less fixed. If the joint be opened without sufficient drainage and without antiseptic treatment, decomposition of the pus in the cavity takes place, and the ordinary results of septic arthritis follow. The exact process by which the joint becomes infected, and what it is that determines the particular joint or joints which are attacked, is not certainly known. The pus contained in the articulation in all forms of infective arthritis is very irritating and contains microorganisms in large numbers. (See also *Pyæmia*, vol. i. p. 917.)

In scarlet fever it is not uncommon for the patient to suffer from slight swelling and pain in the joints resembling rheumatism. This subsides without suppuration, and is probably distinct from the pyæmic affection just described.

Acute arthritis may occur as a complication also of gonorrhœa, but it is a rare occurrence. The milder forms of inflammation of the joints, included under the term gonorrhœal rheumatism, will be described in the chapter on Gonorrhœa. When the affection assumes a destructive form, it is probably due to pyæmic infection.

Acute Arthritis from Exposure to Cold. Acute Rheumatic Arthritis.—This is a somewhat rare affection. After exposure to cold, especially to from sleeping in the open air after being heated by violent exertion, the patient is seized suddenly with acute febrile symptoms, sometimes preceded by a rigor. At the same time swelling, with intense pain, commences in one joint, most commonly the knee. The symptoms at first so closely resemble an attack of acute rheumatism that these cases are commonly first admitted in hospital practice into the medical wards and subsequently transferred to the surgical. The distinction from acute rheumatism is made by observing the following points: the skin is hot and dry, the profuse sweating of rheumatic fever being absent; the affection remains limited to the single joint attacked, and the symptoms are much more severe than in ordinary rheumatism. The ligaments are early implicated, and there is little recognizable effusion into the joint; the pain is most agonizing, and is of the character already described as occurring in acute arthritis. Pus may form in the joint in a few days from the commencement of the attack, but, under proper treatment, the symptoms usually subside gradually, and the patient slowly recovers, after weeks or months, with the joint always stiffened, and usually firmly ankylosed, sometimes even by bone. The exact cause of the disease is not certain; from its sudden invasion, and its arising from exposure to cold, it has been termed rheumatic, but the evidence of its being actually related to acute rheumatism is not clear. Volkmann describes it under the name of Acute Croupous Arthromeningitis, and states that it is characterized by an abundant coagulable exudation both into the synovial cavity and the articular structures forming the joint. From the facts that if suppuration takes place the cartilages are rapidly destroyed, and that in other cases bony ankylosis occurs subsequent, probably, to such destruction, Bradie and Mayo believed that structure to be primarily affected, and named the disease Primary Acute Ulceration of Cartilage. At the present time ulceration of

cartilage is believed to be invariably secondary to mischief commencing in the vascular structures.

Acute Arthritis secondary to Disease of the Bones.—Chronic diseases of the bones most commonly, when they extend to a neighboring articulation, lead to a chronic disease of the joint, assuming the form of white swelling to be presently described. The only exception to this rule is the scrofulous abscess in the head of a long bone. This may perforate the cartilage, allowing its contents to enter the joint, and acute arthritis, ending rapidly in suppuration, may be set up. If the cavity has been already opened externally and contains decomposing pus, septic arthritis of the most acute form always follows perforation of the cartilage. The perforation of the cartilage in these cases is effected by a process of ulceration identical in character with that already described as occurring in acute arthritis commencing in the joint, the only difference being that it proceeds from the deep instead of the articular surface of the cartilage.

Acute inflammatory processes when extending from the bone to the joint always set up acute arthritis. Acute infective periostitis or osteomyelitis of the shaft (*Acute Necrosis*, p. 292), usually stops at the epiphyses, and, consequently, seldom causes disease of the neighboring joints. This rule is, however, not absolute, and exceptional cases are met with in which the articulations become affected. In these there is at first abundant effusion into the cavity of the synovial membrane; this rapidly becomes purulent, and destruction of the cartilages and softening of the ligaments quickly follow.

Acute osteomyelitis attacking the growing bone in the epiphysis and usually terminating in its necrosis, or, as it is termed, *acute epiphysitis*, is a not uncommon cause of acute arthritis in young subjects. The causes of this affection are not always evident, sometimes it is attributed to injury. On examining a joint affected in this way, the appearances already described as characteristic of acute arthritis with ulceration of the cartilages are met with. On making a section of the epiphysis from which the disease started, the bone contained in it will often be found forming a sequestrum bathed in pus, the cavity in which it lies communicating with the joint by an ulcerated track through the cartilage. In other cases the epiphysis may be separated from the shaft. Acute epiphysitis is probably in most cases an infective inflammation closely allied to acute infective periostitis and osteomyelitis.

Syphilitic epiphysitis and its effects on the joints has been already described (vol. i. p. 1981).

Acute Arthritis from Diseases of the Soft Parts external to the Joint.—

Abscesses arising from any cause in immediate contact with a joint may burst into its cavity. When this happens, acute arthritis with destruction of the articulation invariably follows. This accident may occur in acute inflammation and suppuration of the bursa in the neighborhood of a joint. In pyæmicæous erysipelas the joints are occasionally opened where the ligaments are in close contact with the subcutaneous tissue.

Fig. 329.—a. Caries at Head of Tibia.

b. Perforation of Cartilage.

Acute Arthritis of Infants.—Under this name, T. Smith has described a form of acute arthritis unconnected with syphilis or injury, not uncommonly met with in very young children. It is sudden in onset, and runs a rapid course, ending in suppuration. It is most common in the knee, hip, and shoulder. The first symptom is restricted movement with pain, rapidly followed by swelling, and the formation of pus. In some cases two or three joints are affected. If the abscess is opened early, recovery may take place; ankylosis rarely results, but more commonly a weak movable joint is left. The disease is fatal in a considerable proportion of cases. In the 21 cases recorded by T. Smith, the ages of the patients were as follows: 8 under 1 month, 4 under 2, 7 between 2 and 6, and 3 over 6 months. The post-mortem examination of the fatal cases showed rapid loss of substance in the articular end of one of the long bones entering into the joint. Acute Arthritis of Infants does not seem to be a separate disease. Some of the recorded cases were probably pyæmic, arising in very young infants from infection from the umbilical cord; others were instances of acute epiphysitis occurring in young children.

Senile Acute Arthritis.—There is occasionally, but very rarely, met with a form of acute arthritis occurring independently of any external cause, but apparently due to necrosis of the cartilages, from simple loss of vitality in old persons of feeble constitution. I have seen it in the joints of the foot, the ankle, and the sterno-clavicular articulation. It resembles in this respect that form of senile necrosis of bones described at p. 301. In the senile arthritis now alluded to, the pain is very acute, the enlargement of the joints considerable, the wasting of muscle rapid and great. The constitutional disturbance is proportionately severe. The joint that it most frequently affects is the knee. I have seen it also in the wrist. This form of arthritis must not be confounded with the dry rheumatic arthritis of old people. It differs from this form of the disease in the acuteness of its local symptoms, and the severity of the constitutional disturbance. It is often mistaken in the first instance for gout; but the rapidity of the process, the formation of pus within and around the joint, the necrosis of the contiguous bones, and the separation of the incrusting cartilages, all indicate the different nature of this affection; which, so far as the joint itself is concerned, is incurable, and which may terminate in the loss of the patient's life.

On examining the joint after removal, the cartilages will be found to be ulcerated, the synovial membrane softened, swollen, and injected; the ligaments softened, and the articular osseous ends congested.

REPAIR.—Should the patient recover from acute arthritis without removal of the joint by amputation or excision, the processes of repair will vary with the extent of the mischief done before the arrest of the disease. The inflamed ligaments seldom recover their normal condition. The inflammatory products with which they are infiltrated are partly absorbed, and partly developed into dense fibrous tissue. This process is accompanied frequently by some contraction, so that when it is completed the natural mobility of the joint is more or less interfered with. Should the position of the joint during the attack have led to relaxation of any ligament, as, for instance, of the ilio-femoral from flexion of the hip, the ligament becomes shortened as the joint recovers, so that the position assumed during the acute stage becomes a fixed one.

In the synovial membrane the inflamed surfaces, which have lost their endothelial covering and become covered with granulation-tissue, adhere to each other wherever they are in contact, and thus the synovial pouches become obliterated. If the cartilages have been but very superficially ulcerated, they may become again smooth without forming adhesions between the

opposed surfaces. If, however, the destruction has gone on to the extent of the formation of granulation-tissue on the surface of the cartilages, the opposed granulating surfaces coalesce, the new tissue becomes developed into normal fibrous tissue, and the joint is permanently stiffened. This condition is described as fibrous ankylosis. If the cartilage has been completely destroyed the opposed granulations on surfaces of the bones coalesce and develop into bone, and thus, osseous ankylosis results. In no circumstances does cartilage when once destroyed become regenerated.

TREATMENT—In the treatment of *acute arthritis*, perfect rest of the articulation is at the first moment. Unless this be secured, no other treatment can be of any avail. The limb should be comfortably supported on pillows, or lined by well-made and softly padded splints, or slung in a cradle. For the hip, knee, or ankle, Thomas's hip and knee splints will be found most efficient. But not only is rest, amounting to absolute immobility of the joint, imperatively required as the first means of cure, but there is a second means which is almost of equal importance, with the view of removing pain, and preventing destructive disorganization of the articulation and consequent ankylosis—I mean slight extension of the limb, so as to separate the articular surfaces very slightly from one another, and to prevent the excessive and agonizing pain that results partly from the pressure of one inflamed articular surface against the other, by the tonic contraction of the muscles of the limb, partly from the spasms that shake the limb and body from time to time, when the patient fails to sleep. These pains are not relieved entirely by simple rest and pressure—more especially that pain which results from the spasmodic action of the muscles of the limb; but they are usually at once removed by extension, by means of a weight attached to the lower part of the limb. This is particularly the case in inflammations of the hip- and knee-joints. It is in these cases that the weight-extending apparatus, combined with perfect rest, is so advantageous. The weight should be proportioned to the age of the patient. In use will often at once relieve pain, and enable the sufferer to procure sleep. Fomentations and the usual topical soothing treatment may be combined with these means. In the acute stage of the disease, small doses of calomel and opium in pill may be useful, and at the same time the patient must be confined to liquid food without stimulants. Leeches applied freely to the joint frequently relieve the pain and diminish the acuteness of the symptoms, when the disease is not due to a septic or infective process.

Should these means be successful in arresting the progress of the disease before suppuration takes place, the inflammation often continues in a sub-acute form and some modification must then be made in the treatment. In this condition rest, absolute and immovable, is equally imperative as in the acute stage, and may be secured in the same way. At the same time the joint may be repeatedly blistered; but in many instances most benefit will be derived from the application of the actual cautery. This agent, when properly applied, yields much more certain and successful results than any other form of counter-irritation with which I am acquainted. The patient having been anesthetized, a cauterizing iron, heated to a black-red heat, should be rapidly drawn over the diseased articulation in a series of parallel lines across which an equal number of crossbars are again drawn, so as not to destroy the whole thickness of the true skin. A good deal of inflammation is thus set up, followed by slight suppuration. When this has subsided, the application of the hot iron may, if necessary, be repeated; in this way the deep gnawing pain will usually be removed, and suppuration of the joint may be averted. For counter-irritants to be of any use, they must be employed before suppuration has set in; it is only torturing the patient unnecessarily to have recourse to these agents when once pus has

formed in the articulation. In order that full benefit should be derived from this plan of treatment, it must be persevered in steadily for a considerable length of time, and should be combined with a moderately antiphlogistic and alterative treatment. With this view, the perchloride of mercury, in doses of from one sixteenth to one-twelfth of a grain, may be advantageously given with the compound decoction of sarsaparilla, or, if there be much debility, with the compound tincture of bark: good food and stimulants being combined with it, in proportion to the increase of the debility. As the inflammation about the joint subsides, a tonic plan of treatment on ordinary medical principles should be substituted for that which had previously been employed.

During the subacute stage, if it be thought necessary to apply counter-irritation, absolute rest of the joints of the lower limb may be obtained, without confining the patient to bed, by the use of Thomas's hip or knee splint. (See Diseases of the Hip and Extension of the Knee.) If it be thought unnecessary to apply any counter-irritation, the inflamed joint may be efficiently stented by the application of the starch or plaster bandage, the patient then being allowed to move about on crutches or in a chair. In disease of the joints of the foot, the patient may walk on a pin wooden leg resting on the bent knee.

With respect to the local treatment of the inflamed joint in the later stages of the disease when it has assumed a *chronic* form, it may be stated generally that so long as it is tender on pressure, applied perpendicularly or laterally, so long as there is any loosening of the ligaments, or pain increased by movement, it must be kept absolutely at rest in splints or by a starched or plaster bandage. During this period great care must be taken to keep the joint in the position which will be most useful to the patient in after life, should it become stiff; the straight one for the knee and hip, and the semi-flexed for the elbow. In many cases it may be useful to strap the joint firmly, in the way recommended by Scott. This plan of treatment consists in spreading on pieces of lint the strong mercurial ointment, to every corner of which a drachm of camphor has been added; strips of soap-plaster spread upon leather are then cut of a proper length and breadth, and the joint is firmly and accurately strapped up, the limb having previously been bandaged as high as the joint that is strapped. This dressing may be left on for a week or two, until it loosens or gives rise to irritation; over the whole a starched bandage may be applied. In many cases I have found it advantageous to strap up the joint with a plaster composed of equal parts of the *empastrum ammoniaci cum hydrargyro*, and the *empastrum saponis* or *berberidinis*. These applications not only fix the joint and promote the absorption of the inflammatory products within and around it, but by acting as gentle counter-irritants, remove the remains of the inflammation that may be going on within it. If recovery have left the joint stiffened without being actually ankylosed, the natural movement must be restored by warm bathing, fomentation, friction, and passive motion. Warm water, in any way applied, is particularly and, indeed, singularly useful in a way difficult of explanation in restoring the mobility of stiffened joints. Passive movement must be undertaken with great caution, and not until every trace of active inflammation has passed away. It is better to keep the limb fixed a month or more longer than is absolutely necessary than to begin passive movement a day too soon. The chances of ankylosis are only increased and the chronic inflammation prolonged by abandoning the treatment by perfect rest before the proper time.

Should the treatment fail to prevent suppuration, the prognosis becomes far more unfavorable, especially when large joints, such as the knee or hip,

are affected; so likewise, when the articular ends of the long bones are diseased, it is seldom that the joint can recover itself, as caries or necrosis are complicating the arthritis and keeping it up. When the articulation is very sinuous, as in the carpus, or when a number of small joints communicate with one another, if not directly by synovial membrane, at all events indirectly through the medium of ligament and of fibrous tissue, as in the tarsus, a cure can rarely be obtained. As soon as the presence of pus is recognized, steps must be taken to let it out completely, and to drain the cavity thoroughly. It is important that this should be done if possible before the capsule gives way and the pus becomes diffused in the surrounding parts.

When distinct fluctuation is felt and the cavity of the articulation is evidently full of fluid, if there be any doubt as to its nature, the joint should be punctured with the aspirator. If the fluid removed is thin, serous pus mixed with synovia, the fomentations and other local means of treatment may be continued, and aspiration repeated if the joint fills again. If thick pus is withdrawn, an opening should be made at once and the cavity drained. If the skin is reddened at one part, under which fluctuation is very distinct, the presence of pus is certain, and aspiration will be of little use.

An abscess in a joint should be freely opened by one or two lateral incisions, extending fairly into the synovial cavity, so as to afford a free exit for the pus. The practice of making free incisions into a suppurating joint, as advocated by Gay, was a great improvement on the former method of merely puncturing it. The small aperture that was formerly made, without any antiseptic precautions, admitted air, in consequence of which the pus became offensive and irritating, and, being unable to escape freely gave rise not only to much local mischief, but to severe septic fever. By laying the joint open freely, even when no special antiseptic treatment was adopted, much of this was prevented; exit was given freely to the pus through one or two incisions extending the whole length of the articulation; the septic poisoning from pent-up and putrid matter was prevented, and in many cases healthy granulations sprang up in the cavity and recovery took place with an ankylosed joint. The chances of this successful termination resulting are very greatly increased by the adoption of some efficient method of antiseptic dressing. The irregular cavity of a joint is difficult to drain perfectly even with the freest incisions, and consequently it is of great importance that such fluid as remains behind should not be allowed to decompose. The use of the carbolic spray, though not essential, will render the prevention of decomposition more easy and more certain. By the combined use of antiseptic drainage and rest most excellent results are obtained, and excision of the joint or amputation of the limb usually avoided. It is more especially in the knee, elbow, and hip, that this practice has yielded such good results. In some cases, even when the joint has been perfectly loose and grating, by perseverance in proper treatment a good and useful limb may be left. Should decomposition take place, profuse discharge followed by hectic or chronic septic poisoning comes on, and pyæmia is not unfrequently developed; if the patient escape these dangers the joint may become useless or cumbersome, and its removal by amputation or excision must be practised. When an attempt is made to save the joint after suppuration has taken place, very special attention will be required, in consequence of the softening of the ligaments, to prevent displacement of the osseous surfaces either laterally or antero-posteriorly; this may be produced partly by the weight of the limb and partly by the traction of the muscles. Any neglect of proper precautions in the more minute details of the application and adjustment of proper appa-

may be followed by a very considerable amount of deformity. Should the limb already unfortunately have assumed a faulty position, in consequence of the Surgeon neglecting to support it properly in splints in the early acute stage, the patient may be anesthetized, and the limb gently and gently placed in such a position as will be most conducive to his after comfort.

With regard to the treatment of the special forms of acute arthritis, little need be said. That of *acute septic arthritis* from a wound has already been described. In *Pyemic Arthritis*, most commonly little can be done owing to the constitutional condition of the patient, but should there be no visceral complications a cure not unfrequently results after free antiseptic incision, drainage, and rest. Ankylosis almost invariably results. In *Acute Arthritis from Cold*, perfect rest, leeches, and hot fomentations must be tried. Should suppuration take place, free incisions may be successful in saving the joint. In *Acute Arthritis secondary to disease of the bones*, the results of treatment are not very satisfactory. An attempt may be made to save the joint by removing sequestra and treating the carious surface as described in the chapter on Diseases of Bones, but it often fails, and amputation or excision becomes necessary. In *Acute Arthritis of Infants*, the joint must be laid freely open as soon as pus forms, and by this means the limb can usually be saved. In *Subtle Arthritis*, the treatment must be conducted on ordinary principles of rest, fomentations, opiates, and supports. But at last, in order to prevent destruction of life by pain and exhaustion, the question of amputation may arise; and, serious as this may be in old people, it will be the only alternative and chance of escape from a painful death.

CHRONIC STRUMOUS ARTHRITIS, OR WHITE SWELLING.

By **White Swelling** is meant a very chronic form of arthritis occurring in scrofulous subjects. It was described by Sir Benjamin Brodie under the name of **pulpy degeneration of the synovial membrane**. By modern German writers it is termed *fungous inflammation of joints* (*fungöse Gelenkentzündung*), and more recently, for reasons which will be stated hereafter, it has been proposed to call it **tubercular arthritis**.

SYMPTOMS.—This disease in many cases supervenes slowly on some slight injury, as a twist, or blow, or strain, but in others no definite cause can be assigned for its appearance, and the exact date of its commencement is often difficult to ascertain. It may commence with an acute synovitis in a strumous subject, assuming its peculiar character at a later period. It is especially liable to happen in children and females. The disease begins gradually with some pain and stiffness in the joint, causing a slight limp in walking if a joint in the lower limb is affected. The pain is increased after any extra exertion, and may then be severe enough to oblige the patient to rest for a day or two, when the symptoms generally subside. If the joint be examined during this stage, there will usually be found some slight limitation of movement, complete extension or flexion causing pain. If the joint be superficial, as the knee, elbow, or ankle, it will be seen to be swollen. The natural hollows are less clearly marked than in health, or even completely obliterated. The swelling at this stage takes the form of the distended synovial cavity, as in synovitis with effusion, but it does not give the same sense of fluctuation, being semielastic and pulpy. Sometimes, however, it is so soft that it is readily mistaken for fluid, even by the experienced hand. In the knee it may be distinguished by observing that, though the patella is raised, it cannot be pushed down with a distinct concussion on the femur, as in synovitis with effusion. As the disease advances the joint becomes more

enlarged, and as the ligaments become implicated the swelling loses the outline of the synovial membrane and assumes a more rounded form, the bony prominences being effaced by a uniform, doughy, semielastic or pulpy swelling. The integuments covering it preserve their white color. There is usually but little pain felt when the limb is at rest, but motion becomes more and more painful, till it is no longer possible to use the limb. The position assumed by the limb at this time is that in which the patient has most ease, viz. that of semiflexion, and with this there is a considerable degree of stiffness and rigidity. In this stage the inflammation commonly extends to the periosteum covering the articular ends, which become slightly enlarged by deposit of new bone from osteoplastic periostitis. The degree to which the articular ends are enlarged is very difficult to estimate, as they are usually considerably obscured by the swelling of the surrounding soft parts, and in consequence of the wasting of the muscles from disease, the articulation appears more swollen than it really is. If the disease continues to progress, swelling of the limb sets in at night, a symptom which is generally regarded as indicating that destructive changes are taking place in the cartilages. After these symptoms have persisted for a varying time the swelling becomes more pronounced at one part, fluctuation becomes manifest, and the skin is rednessed. Finally, if not anticipated by surgical interference, the abscess bursts, discharging unhealthy pus mixed with curdy masses. Before this takes place it may reach a considerable size and burrow for some distance from the articulation. The abscess does not necessarily occupy the whole cavity of the joint, for, as will be pointed out in describing the pathology of the disease, no cavity may exist by the time the abscess forms, the whole articular space being filled up with a mass of unhealthy granulation tissue, in the part only of which the suppuration may have taken place. In other cases the abscess may form outside the joint, superficial to the ligaments. After the abscess has burst, its cavity may gradually contract and heal, but more commonly a sinuous track is left leading to the diseased joint. In other cases, especially if the abscess but incompletely empties itself, decomposition of the discharges sets in, the granulation-tissue filling the cavity of the joint may rapidly break down, and the disease then assumes the form of acute septic arthritis (p. 486, vol. 1.), with severe pain and rapid destruction of such cartilage as may have remained undestroyed at the time the chronic abscess burst. The limb swells and becomes oedematous, and other abscesses form around the joint. The ligaments become further softened, grating can be felt in the joint, and the articular surfaces become displaced.

The local phenomena of white swelling may thus be divided into three stages: first, that in which the disease is limited chiefly to the synovial membrane and the swelling assumes the form of the synovial cavity; secondly, that in which the ligaments, cartilages, and articular ends of the bone become implicated, and the swelling becomes oval or rounded; and, thirdly, the stage of suppuration.

The constitutional symptoms vary in the different stages of the disease. The general health does not appear to suffer in the first stage beyond some local febrile disturbance during exacerbations from over-exertion of the joint. In the second stage also, the general health is but slightly impaired, except from want of exercise, and at the later period from want of rest if nocturnal startings set in. In the third stage there is progressive loss of strength. Even when the suppuration is very chronic there is usually some slight evening elevation of temperature, seldom, however, exceeding 101° F. After the abscess has burst, the constitutional symptoms become more severe, hectic may speedily set in, and tubercular disease of other organs, such as the lungs, may carry off the patient.

PATHOLOGICAL CHANGES.—The pathological changes that occur in this swelling have been very accurately described by Billroth. In the earliest stages that have been observed, the synovial fringes are swollen and the membrane generally thicker than natural, and hyperæmic. There is generally no increase of secretion, but the synovia is often slightly turbid. I have once had the opportunity of examining a joint in this stage in a case of disease of the knee, in which, at the request of the physicians in attendance, I amputated at a very early period, in the hope of relieving very severe epilepsy from which the child was suffering. The appearances observed were exactly those described by Billroth, and were limited to the synovial membrane, the other structures entering into the articulation being apparently healthy. As the disease advances, the synovial membrane becomes thicker, and more vascular, its natural smooth surface is lost, and soft spongy granulations spring up upon it. This change is especially marked in the synovial fringes. These form soft masses of granulation tissue which fill up the angles between the articular surfaces and gradually creep over the cartilages. Where two granulating synovial surfaces are in contact, as in the pouches of the knee-joint, they coalesce, and thus the cavity of the joint becomes gradually obliterated. It is in consequence of this limitation of the disease to the synovial membrane in the early stages that the swelling of the joint, observed clinically, takes the form of the distended articular cavity, as in simple synovitis with effusion. As the disease advances, the chronic inflammation extends to the ligaments and capsule, which becomes infiltrated with the inflammatory products, and swollen and lardaceous in appearance; and later on the areolar tissue surrounding the joint is similarly affected. It is owing to this that the swollen joint loses the form of the distended synovial membrane which characterized the earlier stages, and becomes rounded or oval. Simultaneously with the affection of the ligaments, the growth of the granulation tissue within the joint continues until the synovial membrane may come to be represented by a soft pulpy mass of granulation tissue from half an inch to nearly an inch in thickness. The growth gradually spreads over the cartilage, covering it like a veil. If an attempt be made to remove this it will be found that the advancing edge can be raised with the handle of the scalpel for about one-eighth of an inch, beyond which it will be adherent to the cartilage. The advance of the granulation-tissue over the cartilage is compared by Billroth to ivy creeping over a wall, and becoming gradually attached by its roots. If the granulation-tissue be scraped away, it will be seen that the cartilage is being gradually consumed, its place being occupied by the vascular new tissue. Finally, it is completely perforated, and the bone beneath becomes similarly affected. In the bone the process assumes the form of rarefying osteitis with exuberant growth of granulation-tissue superficial fungating caries, p. 295. The granulation tissue spreading from the bone extends beneath the cartilage, loosening it from its attachment; and, as now it is attacked on both sides, its destruction proceeds more rapidly than before. At the same time, the destructive process may extend to a varying depth into the cancellous tissue of the articular end of the bone. The periosteum usually shares in the disease, the inflammation assuming the osteoplastic form, and leading to the deposit of irregular masses of bone on the articular ends, chiefly in the immediate neighborhood of the joint. At this stage no articular cavity remains; the joint is represented merely by the articular ends of the bone more or less extensively denuded of cartilage, embedded in a soft pulpy mass of granulation tissue, surrounded by the infiltrated and softened ligaments. When the granulation tissue reaches the thickness of from a quarter to half an inch, its vascular supply becomes inefficient for its healthy nutrition, and fatty degeneration sets in

in the parts most distant from the base of supply. It is from the appearance of the mass of unhealthy granulation-tissue that the disease received its name of "pulpy degeneration of the synovial membrane." The soft grey tissue is pink in color, marked by yellowish patches of fatty degeneration and brown areas from old hemorrhages. The fatty degeneration is followed sooner or later by softening, and thus a chronic abscess with flocculent curdy contents is formed. This frequently occurs in one or more local centres, without implicating the whole mass of granulation-tissue. Thus, in the knee, it frequently occurs in the site of the synovial pouches above the joint.

The disease does not always begin as just described in the synovial membrane. In many cases, it is impossible in the present state of our knowledge to say in what proportion, it commences in the articular end of one of the bones, as superficial fungating caries, immediately beneath the cartilage. In these cases, so soon as the cartilage is perforated, the changes just described commence in the synovial membrane and completely conceal all evidence of the primary bone disease. Clinically it may be said to be impossible to distinguish accurately one form of the disease from the other.

On microscopic examination, the diseased structures present the following appearances. The ligaments show the ordinary changes observed in inflamed fibrous tissue. The fibres are separated from each other by inflammatory products, composed chiefly of small round cells. When the process is very chronic, new fibroid tissue also may be found. The cartilages show changes similar to those already described in acute arthritis. Before suppuration has taken place, ulceration both without and with evident proliferation may be present (see p. 340). The destructive changes may be observed on either surface, according as the disease commences in the synovial membrane or the bone. In the later stages, after perforation of the cartilage, both surfaces may be similarly affected. After suppuration has taken place, necrosis of cartilage with disintegration (p. 339) also may be met with. The bones present the appearances already described as being met with in fungating caries (p. 29). The chief interest attaches, however, to the microscopical appearances of the pulpy granulation-tissue which has replaced the synovial membrane and fills the cavity of the joint. The structure of this tissue has been made the subject of investigation by Köster, König, Volkmann, and Hueter, among others in Germany, and by Croft and Greenfield in this country, and all are substantially in agreement as to its nature. The chief bulk of the tissue is made up of small round cells, united by a structureless intercellular substance and abundantly supplied with vessels; in other words, of ordinary granulation-tissue. Scattered through this are numerous tubercle nodules, differing in no respect from those met with in other structures (vol. i. p. 1010). In other parts the granulation-tissue has undergone fatty degeneration and become reduced to a structureless granular mass. Croft and Greenfield pointed out that most commonly the diseased tissue may be divided into three layers, which merge into each other: first, the layer nearest the source of vascular supply (the bones or capsule of the joint), composed of ordinary granulation-tissue; secondly, a layer containing numerous giant cells, surrounded by "epithelioid-cells" and lymphoid corpuscles arranged in the way ordinarily observed in nodules of tubercle, and forming non-vascular areas in the surrounding vascular granulation-tissue; and, thirdly, the layer most distant from the base of vascular supply, in which fatty degeneration is taking place, and all definite structure is lost. The tubercle nodules are not absolutely limited to the middle layer; a few may be found in the first layer in the swollen ligaments and the medullary tissue of the diseased cancellous tissue. The presence of this structure is so

constant that it may be regarded as characteristic of true white swelling or strumous arthritis. In 72 cases examined by König it was found in 67, and in the remaining five the material for examination was deficient, so that no conclusion could be arrived at as to its presence. Croft and Crocchietti and other observers agree as to the constancy of the presence of tubercle. The number of giant cells varies in different cases, but they are always present. Since the discovery of the tubercle bacillus by Koch, the presence of the organism in the pulpy tissue of white swelling has been frequently demonstrated. Further proof of the tubercular nature of the disease has been obtained by Hueter and others from inoculation experiments carried out on animals. The statistics of white swelling show, moreover, that in a very large proportion of fatal cases death takes place from general tuberculosis. Albrecht has lately published some statistics, in which it is shown that, out of 116 fatal cases, in 64 death occurred from tuberculosis.

At the present time, therefore, it may be said that the evidence of the tubercular nature of white swelling is almost conclusive; but it has not been determined certainly whether the development of tubercle is the primary change in the disease, or whether a chronic inflammation of a simple character precedes the appearance of the tubercle, the inflammatory products forming a suitable nidus for its development.

TREATMENT.—In the treatment of white swelling, we must bear in mind that we have to manage a truly scrofulous inflammation and its effects. Our first object should be to prevent, if possible, the occurrence of suppuration. In the early stage, when the affection has come on insidiously, without any very active symptoms, we must trust to general anti-strumous treatment—to the influence of good diet and sea-air, and to the administration of tincture of cod-liver oil, and iodine.

In the local treatment there are three great principles to be carried out. 1. *Rest, with perfect immobility* of the joint, is by far the most important element in the treatment, without which all the efforts of the Surgeon to prevent suppuration and disorganization of the joint will be futile. 2. *Compression* by means of bandages, strapping, or splints, will aid in the absorption of the inflammatory products in and around the joint. 3. *Counter-irritation* by means of blisters or the actual canter may be employed. These, to be of real service, should be used before suppuration has occurred; after this they are of no use. The limb should be put into a position which is not only easy to the patient, but which will leave it most useful should a stiff joint result. If it be one of the joints of the lower extremity that is affected, especial care must be taken that the patient does not bear his weight upon it. If it is the hip or knee that is diseased, the best splints are those invented by H. O. Thomas of Liverpool, which will be described in the next chapter. If the ankle is affected the patient may be allowed to move about, kneeling on a "pin leg," with a trough to support the limb below the knee. In the upper limb, rest is best secured by well-padded leather or gutta-percha splints. In many cases, both in the upper and lower limb, a plaster of Paris bandage over dannel or a starched bandage well lined with cotton wadding will be found a most useful appliance. This kind of apposition will be found to give most efficient support, and will keep the whole of the limb perfectly motionless, so that the patient can take open air exercise, and walk with the aid of crutches, without risk of injuring the diseased joint. In this respect the starched bandage presents great advantages over the stiff leather splints often used. It may readily be cut open opposite the diseased point, so as to admit of the application of proper dressings to it. The period during which it is necessary to maintain perfect rest varies in different cases, but if the disease has advanced beyond the earliest stages many months or

even a year will be required. The period of rest must not be shortened, for fear of causing stiffness of the joint. Imperfect rest from defective apparatus, by prolonging the disease, is a much more frequent cause of permanent impairment of function in the joint. So long as there is any tenderness or pain or marked swelling, rest must be maintained.

During acute exacerbations of the disease, leeches may sometimes be useful, these must, however, be used as sparingly as possible. Should severe starting pains at night be present, without evidence of suppuration, the actual cautery, applied as described on p. 345, is extremely beneficial.

After all inflammation has, in this way, been removed, and nothing but thickening and stiffness of the joint are left, measures may be adopted for removing these conditions, and restoring the flexibility of the articulation by frictions with somewhat stimulating and counter-irritant embrocations, and eventually its strength by douches of sea-water. The swelling and puffiness that are left, together with the debility dependent on relaxation of the ligaments, are perhaps best remedied by the use of Scott's strapping: but pressure should not be applied so long as there is evidence of active inflammation going on in the articulation, which it would certainly increase.

If abscess form, it must be freely opened, with strict antiseptic precautions. The pulpy granulation-tissue may then be scraped out as far as possible with a sharp spoon. If the incision be free enough, it is seldom necessary to introduce a drainage-tube. The iodoform or salicylic wool dressing will be found most useful in many cases, and a small quantity of iodoform may with advantage be introduced into the cavity of the abscess. The dressing will usually require changing after the first day or two, as it becomes soaked by the early discharge, but after this it may frequently be left untouched for one or two weeks, or even a month, unless some discharge soaks through it. If these materials are not at hand, any of the forms of antiseptic dressing described in the chapter on Wounds (vol. i.), may be employed. Poultices should not be applied, as they favor decomposition and increase the suppuration, and the patient's general health will suffer from the exhausting discharge, and hectic may come on. After suppuration has taken place, if the joint can be preserved, the subsequent utility of the limb will depend mainly upon the position in which it is allowed to become ankylosed. In many cases, in spite of treatment, especially in the children of the poor, the disease slowly progresses, leading to complete destruction of the joint. Under these circumstances, excision or amputation is the only resource.

CHRONIC RHEUMATIC ARTHRITIS, RHEUMATOID ARTHRITIS, ARTHRITIS DEFORMANS.

By these terms is meant a chronic disease of the joints of a progressive character—painful, disabling, deforming, and incurable. This disease has long attracted the attention of physicians, and has been described as "rheumatic gout," "mobility of joints," and "deforming arthritis." But little was known of its true nature until its pathology was studied by Professor J. Adams and R. W. Smith, of Dublin, who accurately described it under the name of "chronic rheumatic arthritis." More recently, Dr. Garrod has added much to our knowledge of this disease, and has proposed for it the more accurate name of "rheumatoid arthritis." When it gives rise to much destruction of limb and deformity of joint, as often happens when the hands are chronically affected by it, the name of "arthritis deformans" is given to it.

This disease may commence in any joint, and may continue limited to it, or may extend from one to the other until most of the larger articulations

are involved. It commences usually in the joints of the limbs, and may continue to be confined to them, or it may primarily attack the temporomaxillary articulations or those of the spinal column. It occurs in both sexes with tolerably equal frequency. But some joints appear to be more liable in one sex than in the other. Thus the hip in the male, the knee in the female, is more commonly the seat of the malady.

Rheumatoid Arthritis is essentially a disease of middle age; when once it sets in it will continue for an indefinite period, far into old age.

Rheumatoid Arthritis may affect one or two joints symmetrically, especially when it occurs in persons otherwise healthy and past middle life. It is then usually confined to the larger articulations. In other cases it may attack a number of joints, including the smaller articulations, such as those of the fingers. This form is often termed *polyarticular rheumatoid arthritis* to distinguish it from the more limited or *monoarthritic* affection. It often leads to great deformity, and may entirely cripple the patient. It is met with sometimes at a comparatively early age, especially in anæmic females.

Chronic Rheumatoid Arthritis essentially consists in an organic change of structure in all the various component parts of the affected joint. The starting point of the disease appears in most cases to be the cartilage. The first change observed is a loss of polish and smoothness, gradually increasing till the surface becomes velvety in appearance. Microscopic examination shows that this change is due to the gradual conversion of the matrix into fibrous tissue, the fibrille of which are arranged at right angles to the surface. At the same time multiplication of the cartilage-cells takes place, so that the capsules are found to contain an excess of cells, which, however, retain the appearance of cartilage-cells. The cartilage so altered is gradually worn away by the friction of the diseased surfaces against each other, until the bone is exposed. When this takes place the exposed bone becomes increased in density by the formation of new osseous tissue filling up the cancellous spaces. The new tissue may be true bone with lacunæ, but in many cases it is excessively dense in structure, contains a great excess of lime-salts, and appears to be formed rather by calcification than by ossification of the medullary tissue of the cancellous spaces. The bony surfaces thus exposed are worn away, and greatly altered in shape by the friction of movement; at the same time they become highly polished, like ivory or porcelain—eburnated or porcelaneous as it is termed. In spite of the density of the structures thus formed, it is constantly being worn away by friction as long as motion is left in the joint, the next layer of cancellous tissue then undergoing the same change. These destructive processes commence and advance most rapidly in the central parts of the cartilages, and while they are in progress irregular cartilaginous outgrowths spring from the circumference, forming in many cases flange-like projections from the margins of the articular surfaces. These cartilaginous outgrowths are osseified at an early period, and thus form rounded irregular osteophytes, often reaching a very considerable size and impeding or completely abolishing the movements of the joint. The osteophytes of rheumatoid arthritis differ essentially from those formed round a carious joint. Their form and appearance have been very aptly compared to the guttering of a wax-candle, while the osteophytes round a carious joint have the jagged form of stalactites. The fact that the former are developed from cartilage and the latter from granulation-tissue, forms another distinction between them. Occasionally isolated nodules of ossifying cartilage of a flattened form are found in the sub-synovial tissue beneath the synovial membrane. In the early stages the ligaments and synovial membrane show but little change; but, as the disease advances, the capsule of the joint becomes greatly thickened. The synovial mem-

brane becomes opaque, and its fringes increased in size. In some cases this enlargement of the fringes is very considerable, the separate papillæ reaching a great size, sometimes even half an inch in length. When this condition is very marked the term *Villous Synovial Membrane* is applied to it. In the free extremities of the enlarged papillæ rounded or flattened nodules of cartilage may be formed. These sometimes become broken from their attachments, and form loose bodies in the joint.

In the earlier stages of rheumatoid arthritis there may be a slight excess of synovia which is turbid, but effusion never forms a marked feature of the disease, and hence the term *dry* is often applied to it.

A section of the bones entering into the affected joint show that the cancellous tissue beneath the eburnated surface is more spongy than natural, the spaces being filled with yellow fat. In consequence of this atrophy of the bone, the shape often becomes considerably altered. This is most characteristically seen in the neck of the femur, which becomes shortened and set more at right angles with the shaft than natural.

Suppuration rarely occurs in rheumatoid arthritis. I have seen it only when the disease was developed at an earlier period of life than usual, at from thirty to forty, or when an injury occurred to the affected joint.

Symptoms.—The affected joint becomes partially ankylosed; is swollen, tender, deformed, and useless. It is the seat of constant pain with occasional exacerbations, often very severe and prolonged. The general health may continue fairly good, though life is rendered miserable and barely endurable by pain and decrepitude. One of the most marked features of the disease is the crepitus or crackling felt on moving the joint. In the early stages this is soft, but as the cartilages become destroyed and the bones exposed, it becomes gradually harsher till it may almost resemble the crepitus of a broken bone. When the synovial membrane is villous, there is considerable fulness of the joint with a very fine, soft crepitation in movement.

The **Causes** of rheumatoid arthritis are for the most part very obscure. Long-continued exposure to damp cold, as prolonged residence in a damp house, or on a wet and clayey soil, undoubtedly predisposes to the disease, and in many cases appears to be the direct occasioning cause. The sprain of a joint will in many cases appear to be the local determining cause. The essential cause of the disease is unknown. It is not scrofula, it is not gout, it is not true rheumatism; as Garrod truly observes, it is much easier to prove what rheumatoid arthritis is not, than to give the slightest clue to what it is. It is generally supposed to be dependent upon some form of malnutrition of the system, and to be predisposed to by depressing influences, physical or moral. That deficient or perverted innervation may in some manner lead to rheumatoid arthritis is not improbable, the more so when we consider that a somewhat analogous condition of joint has been described by Charcot as one of the characteristic phenomena of locomotor ataxy.

TREATMENT.—Little can be done to cure, but much to relieve and retard. Rest and the continued application of warm or stimulating plasters will afford relief; and, in many instances, the administration of the iodide of potassium will lessen the nocturnal pain. Smith recommends an electuary composed of guaiacum, sulphur, the bitartrate and carbonate of potash, and ginger, with a small quantity of rhubarb; and I have certainly seen benefit result from the administration of this remedy in some cases. Ammoniacum and cod-liver oil are both extremely useful in some cases. When the disease is once fairly established, and has assumed a very chronic character, it will be found of great importance to give the affected joint as much rest as possible, without confining the patient to the couch or house. This is best effected by his wearing a proper supporting apparatus. When the hip or

knee is the seat of the disease, the apparatus should consist of a firm leather pelvic band having a steel rod extending down the outside of the foot, hinged angularly opposite the hip, knee, and ankle, and fixed into a socket in the sole of the boot, and properly adjusted by means of straps and mounted leather to the thigh and leg. By the use of this apparatus the weight of the limb is taken off, and all rotatory movement of the hip is prevented, lateral motion being allowed. Thomas's hip- or knee-splint will sometimes be found useful.

Mineral waters and baths are often beneficially used in the treatment of rheumatoid arthritis; those of Wildbad and Franzenbad in Germany, of Aix-les-Bains in Savoy, Buzonnes and the other Pyrenean sulphurous waters in France, Buxton and Bath in this country. That warm douching and bathing may give great relief is undoubted. But that they can cure an organic joint-disease of the nature of rheumatoid arthritis is scarcely within the bounds of probability.

Chronic Rheumatoid Arthritis of the Hip.—This form of the disease commences with pain in and about the joint, increased at night, and especially in damp or cold weather, presenting in this respect the ordinary characters of a rheumatic affection; as the disease advances, the pain, which is continuous, is much increased by standing or walking, and the movements of the joint become gradually more and more impaired. The patient experiences the greatest difficulty in bending the body forwards from the hips; he consequently is unable to stoop, or to sit in the ordinary position, being obliged to keep the limb straightened in nearly a direct line with the trunk. The difficulty in walking, in standing erect, in stooping, and in sitting increases. The trochanter will be felt to be thickened. The limb, at first perhaps slightly lengthened, eventually becomes shortened to the extent of about an inch or more, owing to changes that take place in the head and neck of the bone. The pelvis also assumes an oblique direction, and hence the apparent shortening becomes considerably greater. The knee and foot may either be inverted or everted, and the heel is raised. The shape of the hip also alters considerably, it becomes flattened posteriorly, the gluteal muscles waste so that the fold of the nates diminishes and sinks to a lower level, but the trochanter projects more than natural, and on examination seems larger and thicker than natural (Fig. 530). On rotating the limb, the movements of the bone are extremely limited, and crackling, grating, or crepitous crepitation will often be felt around the joint. As Smith remarks the lumbar vertebrae acquire great mobility. The thigh on the affected side is wasted, but the calf retains its natural size and firmness.

Fig. 530. — Chronic Rheumatoid Arthritis of Right Hip-joint.

Pathological Changes.—On examination after death, the changes already described as characteristic of rheumatoid arthritis will be found. The round ligament is destroyed, and the head of the bone is remarkably altered in shape, being flattened, greatly increased in size, or placed more or less at a right angle with the shaft, sometimes elongated, and always very irregular and tuberculous. The neck is more or less absorbed, and in some cases appears

as if it had undergone fracture. The acetabulum generally becomes enlarged, sometimes of a more or less circular and flattened shape; but in other cases projecting and narrowed at its rim, embracing tightly the head of the thigh-bone (Fig. 511). Both it and the upper part of the thigh-bone become porous, and perforated with numerous small foramina. Masses of bone are commonly thrown out about the base of the trochanter, but more particularly along the intertrochanteric line within the capsule of the joint, and not infrequently in the soft tissue around it. In many cases the apparent increase in the size of the head of the bone is dependent on the deposition of these masses of osseous tissue upon it, rather than on any expansion of the upper articular end of the thigh-bone. These masses of bone constitute one

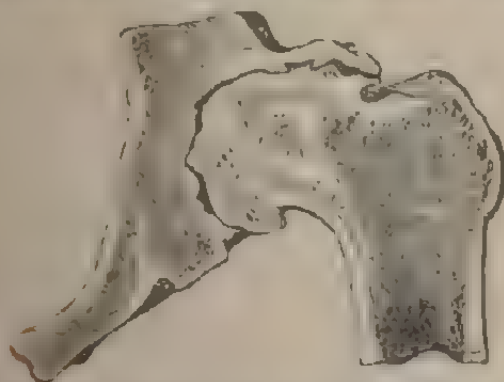

Fig. 511.—Section of Hip-joint Affected by Dry Chronic Rheumatic Arthritis.

of the most important characters of the disease. The muscles and soft structures in the vicinity of the joint are necessarily wasted from disuse.

Disquiescence. It occasionally happens that an individual laboring under this affection, meeting with a fall or contusion on the hip, presents signs of *fracture of the neck of the thigh-bone*, such as shortening, eversion, with some crepitation perhaps, and inability to move the limb. The diagnosis may in general readily be effected by attention to the history of the case, and by eliciting the fact that the symptoms have existed to some degree before the accident, although the pain and immobility may have been increased by it.

Chronic Rheumatoid Arthritis of the Lower Jaw.—Chronic rheumatoid arthritis has also been described by Smith as occasionally affecting the temporomandibular articulation in individuals of rather advanced life. This disease is often symmetrical, and gives rise to an enlargement of the condyle of the jaw, which can be felt under the zygoma, attended with much pain in opening the mouth, a sensation of cracking or grating in the joint, and some enlargement of the lymphatic glands by the side of the neck. The pain is generally increased at night, and influenced by the state of the weather. The face becomes distorted, the affected side of the jaw projecting and being pushed towards the opposite side; but when both joints are affected the chin projects, the entire jaw being drawn forwards. This distortion is chiefly owing to the destruction of the articular eminence; for, when this takes place, the external pterygoid muscle draws the jaw forwards and to the opposite side; but when both articulations are equally affected, these muscles displace the jaw forwards; the glenoid cavity becomes enlarged, the fibres cartilage (see p. 294) and the condyle is sometimes greatly thickened and flattened, and always rough, being devoid of cartilage. In such cases there is little to

be done by medicines; but the treatment must be conducted on the same principles as in the same affection attacking the hip.

Chronic Rheumatoid Arthritis of the Shoulder.—When it affects the shoulder, chronic rheumatoid arthritis gives rise to a considerable enlargement of the head of the humerus, wasting and rigidity of the deltoid, and inability to move the elbow upwards, except by the rotation of the scapula on the trunk. In fact, the scapulo-humeral articulation being fixed all movements of the shoulder are effected through the medium of the scapula, which becomes more mobile than natural. The articulation is the seat of much pain, lacerating at times, but generally gnawing and intermittent, being dependent on the state of the weather, and greatly increased in cold and wet seasons. The whole of the arm becomes wasted, and weakened in power. In two instances I have seen this disease in young and otherwise robust and healthy men, between twenty and thirty years of age, coming on without any apparent cause. In both cases the joint continued permanently rigid, though the pain was relieved by the use of the iodides and by local counter irritation.

DISEASES OF JOINTS OF CEREBRAL OR SPINAL ORIGIN.

The so-called *arthropathies* occurring as the result of diseases of the central nervous system may be divided, according to Charcot, into two classes.

1. Arthropathy of Paralyzed Limbs.—Acute or subacute inflammation with considerable swelling from effusion into the joint, and more or less severe pain, is occasionally observed in the articulations of limbs paralyzed from acute or subacute inflammation of the spinal cord. Mitchell has observed it in paraplegia from Pott's disease, Virgès, Joffroy, and Sir William Gull as the result of paralysis from traumatic lesion of the cord. Scott Alison, and others have also met with a similar affection of the joints in limbs paralyzed from circumscribed cerebral softening, or intracerebral hemorrhage. It comes on at the same time as the contraction of the muscles commences, usually fifteen days to a month after the paralysis has set in. It has no tendency to end in suppuration.

2. Arthropathy of Ataxic Patients, or Charcot's Disease.—This condition was first described by Charcot. It occurs in patients suffering from locomotor ataxia, setting in without appreciable cause, usually at that period of the disease when want of coordination in the muscular movements becomes apparent. It commences with a general and often enormous swelling of the limb, commonly without pain or fever. After a few days the general swelling disappears, but the joint remains distended with fluid. Sometimes the bursa in the neighborhood of the articulation are also distended. The fluid if drawn off is found to be transparent, and of a pale lemon color. At the end of some weeks or months the swelling subsides, and the joint may return to its normal state. In the more typical cases, however, crackling appears on movement a few weeks after the commencement of the attack; the ligaments become relaxed as the effusion is absorbed, the osseous surfaces become altered in form by wearing away, and consecutive dislocations are not uncommon. Even under these circumstances, however, some degree of mobility is left in the limb. The joint most commonly affected is the knee, then comes the shoulder, then the elbow, the hip, and the wrist. The *pathological appearances* found after death are similar to, and in many cases identical with, those already described as being met with in chronic rheumatoid arthritis (p. 354). The chief differences are, first, that the wearing away of the surfaces is very extensive, and the formation of the osseous cartilaginous outgrowths round the articulation is very limited, or even en-

tirely wanting; and, secondly, that true dislocations are common, whereas in rheumatoid arthritis they are very rare, and when present occur, not from relaxation of the ligaments, but from pressure of the bony outgrowths. The *diagnosis* from rheumatoid arthritis is made by attention to the following points: First, its sudden and unexpected invasion; secondly, the abundant effusion in the early stages; thirdly, the frequent occurrence of dislocation; fourthly, the occasional retrogression of the disease; and, lastly, the fact that it occurs in conjunction with the other symptoms of locomotor ataxy, for which I must refer the reader to works on Medicine. The *Treatment* must be conducted on ordinary principles, rest being the most important means of preventing the advance of the destructive processes in the articular surfaces.

ANKYLOSIS OR STIFF JOINT.

Ankylosis is invariably the result of partial or total destruction of a joint by inflammation, and is one of the modes by which Nature effects its repair. It consists in the more or less complete consolidation of the parts around and within the articulation. It is of two kinds: the Incomplete, or Fibrous; and the Complete, or Osseous.

In the *Incomplete or Fibrous Ankylosis*, the stiffness of the joint may be dependent on four distinct pathological conditions, which may be more or less associated: 1, on thickening and induration of its fibrous capsule; 2, on the formation of fibroid bands as the result of inflammation within the joint; 3, in consequence of the cartilages and synovial membrane being in part or wholly removed, and their place being supplied by a fibroid tissue, by which the articular ends are tied together; 4, on shortening of the ligaments on the side of flexion of the joint. The stiffness of the joint may be materially increased by the shortened and contracted state of the muscles around the joint. But this is secondary to, and not an essential part of, the ankylosis. Fibrous ankylosis commonly results from rheumatic or scrofulous arthritis, and is the most favorable result that can be hoped for in many of these affections, especially in the scrofulous. In some cases it arises simply from disuse; the ligaments being shortened, and the limb becoming stiffened in the position in which it has been too long detained.

Fig. 532. Osseous Ankylosis of Hip.

Complete or Osseous Ankylosis is of two kinds. In one, all the soft parts within the joint are destroyed, and the osseous surfaces have coalesced, or are fused together by direct bony union; this is most commonly seen in the hip (Fig. 532), knee, and elbow. In the other kind the bones are united partly by fibrous tissue, and partly by arches or bridges of osseous tissue,

thrown out externally to the articulation, and stretching across from one side to the other. It has been supposed that these masses proceed from the ossification of the ligaments, or even the muscles; but from the irregularity of their appearance, it is evident that they are new formations. The true or osseous ankylosis does not often occur as a consequence of seroful or articular inflammation, but is usually the result of pyæmic or traumatic inflammation in persons of a healthy constitution. It not unfrequently happens, in old-standing cases of diseased joint, that more or less complete ankylosis is taking place at one part of the articulation, whilst caries, or necrosis of the bones, is going on at others. It is usually easy to make the distinction between fibrous and osseous ankylosis; the joint being movable, though perhaps only to a very slight degree, in the false, whilst it is rigidly and unmovably fixed in the true form of the disease. Cases not unfrequently occur, however, in which the rigidity of the structures, muscular and capsular, outside the joint, is so great in the fibrous, and the mobility of the neighbouring bones and joints so free in the osseous, that it becomes very difficult to decide to what degree the joint is stiffened. Here the diagnosis may be made by putting the patient under anesthetics, when, if the ankylosis be fibrous, the joint will be found to yield. In fibrous ankylosis any attempt to move the joint forcibly is usually accompanied by much pain, with involuntary contraction of the muscles connected with the joint, whilst in osseous ankylosis such attempts, unless very forcible, are painless.

TREATMENT.—The treatment of ankylosis is, in the first instance, of a precautionary nature; that is to say, when the Surgeon finds that the establishment of ankylosis is, as it were, the natural means of cure adopted by Nature in a deeply diseased joint, his efforts should be directed to taking care that the joint becomes fixed in such a position as will leave the most useful limb to the patient. Thus, if it be the hip or knee, the ankylosed joint should be in the straight position; if it be the elbow, it should be placed at a right angle, and the hand in the midstate between pronation and supination.

When once ankylosis has occurred, the treatment to be adopted will depend partly on the degree of stiffness, whether it be fibrous or osseous, and partly on the object to be attained, whether this be merely the restoration of mobility in a part ankylosed in a good position, or the remedying of the deformity occasioned by faulty ankylosis.

1. In attempting to restore the mobility of a joint ankylosed in a good position, as of a straight but stiff knee, the Surgeon may usually succeed if the ankylosis be only fibrous (when some degree of movement will always be perceptible in the part), by the employment of passive motion, frictions, and douches, more particularly with warm salt water or the mineral sulphurous springs. In the more obstinate cases, and where the union appears to depend, in some degree, at least, on fibrous bands stretching across the joint, an attempt might be made to rupture these subcutaneously.

Sayre has established an important point in the distinguishing of those cases in which it is necessary to cut a contracted tendon or fascia, and those in which it will yield by stretching without division. It is this; if, when the part is stretched to the utmost point and firm pressure is made on it with the finger, reflex action be induced, then it must be cut. If no reflex contraction ensue, then stretching is sufficient.

2. When fibrous ankylosis has taken place in a faulty position—if, for instance, the knee be bent, or the elbow straight—the first thing to be done is to place the limb in such a position that it will be useful. This may most readily be done by putting the patient under the influence of chloroform, and then forcibly flexing or extending the limb as the case may require,

when with loud snaps and cracks it will usually come into proper position. Should any of the tendons or bands of fascia near the joint appear to be particularly tense, they may be divided subcutaneously. Either some days before the extension is attempted, or else, if it have been carried as far as the rigid state of the tendons will permit, tenotomy may then be practised, and, an interval of a few days having been allowed to elapse, extension may be completed. The muscular contraction will, however, in many cases, yield to gradual extension by means of screw-splints or weights, and thus render tenotomy unnecessary. The inflammation that follows this forcible extension or flexion of the limb, is usually but very trivial; an evaporating lotion and rest will speedily subdue it. Indeed, it is surprising what an amount of violence may be inflicted on an ankylosed joint without any bad consequences ensuing. After the limb has been restored to its proper position, passive motion and frictions may tend to increase its mobility.

3. When osseous ankylosis has taken place, and the position of the limb is a good one, it will generally be wiser for the Surgeon not to interfere; except in the case of the elbow-joint, which, in these circumstances, may be excised with advantage, so as to substitute a movable for an immovable articulation. If the position be faulty, the osseous union may be sawn, drilled, or chiselled, and broken through subcutaneously; or a wedge-shaped piece of the bones may be taken out, and the position of the limb thus rectified.

4. Amputation may be required in cases of faulty ankylosis with so much atrophy of the limb as to render it useless, or in cases in which there is necrosed or carious bone coexisting with ankylosis and rigid atrophy of the muscles of the limb.

LOOSE CARTILAGES IN JOINTS.

It sometimes happens that the synovial membrane of a joint assumes a **Warty Condition**, as the result of chronic disease of the articulation, especially in rheumatoid arthritis. This warty state of the membrane arises from hypertrophy of the fringes, chiefly in the neighborhood of the margin of the cartilages. These may become pedunculated, and pendent into its interior. For this condition, which gives rise to occasional uneasiness and puffiness about the joint, with a crackling or creaking sensation when it is moved, but little can be done beyond the application of discutient plasters and the use of elastic bandages.

Loose Cartilages, as they are termed, may be of three kinds. 1. The so-called *melon-seed bodies*. These are usually numerous, sometimes fifty or more in number, white or brownish in color, and closely resemble the seeds of a melon in form. They are composed most commonly of dense fibroid tissue, and are believed to be due, in many cases at least, to the pedunculated, warty, or villous growths just described as being formed from hypertrophy of the synovial fringes, becoming broken loose from their attachments by the movements of the joint. In other cases it is possible they may be formed from altered blood-clot or fibrinous exudation into the synovial cavity. They are much less common in joints than in sheaths of tendons or synovial bursa.

2. *Fragments of true cartilage*. These may be developed in two ways; first, from the formation of cartilage in the hypertrophied fringes of a warty synovial membrane. In the normal condition a cartilage-cell is present in many of the secondary papillae of the fringes, and it is easy to understand how this can form the starting-point of a cartilaginous growth. In other cases, Billroth believes that they are ossifying cartilaginous growths formed

in the fibrous layer of the synovial membrane in rheumatoid arthritis (p. 354), which have subsequently become loose by the wearing away of the superficial layers of the membrane. This mode of origin is somewhat doubtful. These cartilages are usually flattened, with a lobulated irregular border, and frequently contain true bone in their central parts; sometimes they may be partly calcified, but contain no true osseous tissue. They may attain a size of more than one inch in their greatest diameter. They are usually single, but occasionally four or five may be found in the same joint. There is strong reason to believe that these cartilaginous bodies may increase in size after becoming loose in the joint.

3 Numerous cases have been recorded in which the loose body was undoubtedly a piece of one of the articular cartilages broken off by mechanical violence. These present the ordinary appearance of articular cartilage, and may usually be recognized by their having one smooth surface, while the opposite side has small gritty fragments of bone attached to it, which have been torn from the cancellous tissue beneath. They are always single.

Loose cartilages of all kinds are most commonly met with in the knee, but not uncommonly occur in the elbow or the joint of the lower jaw, and occasionally in the shoulder.

SYMPTOMS.—The severity of the symptoms will to a great extent depend upon the mobility of the loose cartilage, and its consequent greater or less liability to be ripped between the opposite articular surfaces in the movements of the joint. When these bodies are tolerably firmly attached to the synovial membrane, they may merely occasion weakness of the joint, with occasional synovial effusion. When loose they usually give rise to a very distinct train of symptoms. The most marked of these is the very severe pain which occurs in particular movements of the limb. This comes on suddenly, and is often so intense as to cause faintness or sickness. It is usually followed by a degree of synovial inflammation, and by relaxation of the ligaments. These attacks of pain and of sudden irritability of the part come on at varying intervals, as the result of movements of it; they commonly happen in the knee whilst the patient is walking. It is difficult to say to what this severe pain is due. Richet thinks it may be owing to the synovial membrane being pinched between the foreign body and one of the articular surfaces. I think that it is most probably due to the foreign body being drawn in between the opposite surfaces of the joint, when these are separated anteriorly in the act of flexion of the knee, and then, when the limb is extended, acting as a wedge between those, tending to keep them separate and interfering with the complete straightening of the limb. In consequence of this wedge-like action of the loose cartilage, the ligaments are violently stretched, and the sickening pain consequent on this act is experienced, followed, as happens in a violent sprain, by rapid synovial effusion. The sensibility of the ligaments of a joint is of that peculiar nature that it is called into action only when an attempt is made to stretch them, and thus forcibly to counteract or destroy their natural use. Ligaments may be cut without any suffering but they cannot be stretched, either by accident or disease, without the most severe pain. In some cases the loose cartilage can be felt under the capsule, by carrying the finger over the joint, showing back when pressure is exercised upon it, and often possessing great mobility, gliding from one side of the joint to the other, so as to be extremely difficult to fix.

DIAGNOSIS.—The only condition likely to be confounded with a loose body is the displacement of one of the interarticular fibro-cartilages of the knee. The distinction can usually be made by observing that immediately after the sudden attack of pain the knee can be completely extended when it is due

to the presence of a loose body, as this rarely if ever becomes jammed between the articular surfaces; while a displaced fibro-cartilage usually remains out of position until replaced by manipulation or movement of the joint, and until this is effected complete extension is impossible.

TREATMENT. The palliative treatment consists in supporting the joint with an elastic bandage or knee-cap, so as to limit its movements, and thus prevent the liability to recurrence of the attacks of pain; and in this way the fixation and ultimate absorption of the cartilage may sometimes be obtained. This I have several times seen to occur in patients who either refused to be operated on, or in whom an operation was not thought advisable. Any inflammation that has been excited requires to be subdued by proper antiphlogistic treatment. In all operations for the removal of loose cartilages antiseptic precautions of the most rigorous character should be adopted. By their aid joints may be opened and explored, and foreign bodies extracted with a freedom and safety otherwise unattainable.

If the cartilage occasion great and frequent suffering, so as to interfere seriously with the utility of the limb, and if it appear to be of large size, and to be loose and single, means may be taken for its extraction. But it must be borne in mind that, whilst the loose cartilage is at most an inconvenience, though perhaps a serious one, any operation for its removal by which the joint is opened, becomes a source of danger to the limb and even to life. It is far less dangerous, in fact, to leave the foreign body than to perform the operation necessary for its extraction. Hence an operation should not be lightly proposed or undertaken, without warning the patient of the possible consequences that might follow. No operation should be undertaken so long as the joint is in an irritated state, as the result of a recent attack of pain and inflammation; this must be first subdued, and then the operation may be proceeded with; nor should it be done if the patient's health be broken.

The extraction of the foreign body has been performed in two ways; by direct incision into the joint, and by subcutaneous section. The operation by direct incision used to be effected by directing the patient in the first instance to make those movements by which he usually gets the cartilage fixed in the joint. So soon as the Surgeon felt it (as this operation is commonly required in the knee), he pushed it to one side of the patella, where he fixed it firmly with his forefinger and thumb; he then drew the skin covering it to one side, so as to make it tense, and cut directly down upon the cartilage by a sufficiently free incision to allow its escape. The wound, which, when the skin was relaxed, was somewhat valvular, was then closed by a strip of plaster and the limb kept at rest for a few days until the incision was healed. Severe inflammation of the joint less frequently followed this coarse operation than might have been expected, the synovial membrane having probably undergone some modifications that rendered it little liable to this process. It has, however, happened, that acute synovitis running on to suppuration has set in, causing the patient's death, requiring amputation, or leading to ankylosis. In the present day the operation is much more safely performed by the adoption of the antiseptic method. The incision is made directly on the loose body, without any valvular arrangement, and after the operation a drainage-tube is inserted into the wound for a few days until the synovial effusion excited by the disturbance of the joint has passed off. The carbolic spray will be found to give an increased safety in performing this operation. Should it not be used, the wound may be irrigated, and great care be taken to prevent the entrance of air into the articular cavity.

It has been proposed by Chassagnac, in order to obviate the dangers of

direct and open wound into the joint, to remove the loose cartilage by subcutaneous section; this he accomplishes in a way that I have seen practised by Liston, and have often done myself, viz., by passing a tenotome obliquely under the skin, after fixing the foreign body in the way that has already been described, dividing the synovial membrane freely, and then squeezing the cartilage into the areolar tissue outside the joint, where it is firmly fixed by plaster and bandage, and left to be eventually absorbed. Guyranet recommends the same subcutaneous mode of removal of the foreign body from the inside of the joint; but, instead of leaving it to be absorbed, extracts it at the end of eight days, by a fresh incision, from the areolar tissue in which it has been lying.

A most useful modification of this method has been practised by Square, of Plymouth; it consists in fixing the loose cartilage, dividing the capsule subcutaneously over it, and then pressing the foreign body into the opening thus made, retaining it there by a compress and plasters. In operating by this method on the knee, the cartilage should be fixed below and to the inner side of the patella, between it and the head of the tibia; a long narrow tenotome is then introduced obliquely under the skin from a distance of about two inches below the loose cartilage; the capsule of the joint is freely divided, and a space made in the subcutaneous areolar tissue by a slight sweep of the blade, and the loose cartilage is then pressed into the cavity thus made to receive it, and slid along the areolar tissue for about two inches. It is fixed *in situ* with a firm pad and adhesive plaster; the foot and leg are bandaged up to the edge of the cartilage, and the limb is placed in a splint. If no inflammatory symptoms ensue, the cartilage is excised about a week after the operation; or it may be left to be absorbed. By the adoption of these subcutaneous methods, there will be but very little danger of inducing undue inflammation in the joint, the entrance of air being prevented, which, and not the mere section of the capsule and synovial membrane, constitutes the chief risk. Should there be more than one loose cartilage, the operation must be repeated, but not until any inflammation induced by the former one has been subdued. In this way I have successfully removed in succession five loose cartilages from one knee.

NEURALGIA OF JOINTS.

Pain of a severe character is often experienced in or around a joint, closely simulating, but not dependent upon, inflammation or other structural disease. This pain, which is purely neuralgic, may have its origin either in some local irritation of a nerve leading to the sensitive part, or in constitutional disorder of a hysterical character. It is this class of cases, occurring in young women who are either the subjects of hysteria, or are of a highly nervous temperament, that should especially be considered as Neuralgia of the Joints, to which the attention of the profession has been directed principally by the labors of Sir B. Brodie.

SYMPTOMS.—It is generally found that the hip, knee, ankle, or shoulder is the joint affected—the hip and the knee more especially. The neuralgia is usually localized in a particular joint by some slight injury that the part has sustained. But it is important to observe that in these cases the pain often does not develop for some days, or even weeks, after the injury that is the alleged cause of it. Severe pain in the joint is complained of, and the limb is rendered comparatively useless, often with a good deal of distortion or contraction. On examination, it will be found that the pain, which is commonly very severe, is superficial and cutaneous, not existing in the interior of the articulation, nor increased by pressure of the articular surfaces against

one another; and that it is not strictly confined to the joint, but radiates for some distance around it. This pain is often intermittent in its character, and is frequently associated with neuralgia elsewhere, as in the spine; and not infrequently with uterine irritation or disease. The patient sometimes acquires the trick of producing loud snappings of some muscle or tendon which are distinctly audible all over the room whenever she walks or moves. At the same time, it will be observed that all the signs that ought to accompany a severe attack of inflammation in a joint, such as would be attended by a corresponding amount of pain, are absent; there being no painful startings of the limb at night, no heat, redness, or swelling of it, nor constitutional fever and irritation; and the suffering being increased by causes, such as mental and emotional disturbance, that do not influence organic disease. Attention to these various circumstances will usually enable the Surgeon to diagnose the nature of the attack without much difficulty; the only cases in which he will really experience any, being those in which the tissues around the joint have been thickened, indurated, and altered in their characters by the application of counter-irritants; or by some slight articular disease having at some time existed, but having been cured.

CAUSES.—The neuralgia is often referable to the irritation of some particular nerve, either at its origin or in its course. This is particularly the case with neuralgia of the hip and knee, which will be found to be dependent on irritation of the obturator nerve, owing to intrapelvic disease. In one case of secondary abdominal cancer under my care, the patient was seized with the most intense pain in the right hip and knee, so as to lead to the suspicion that these joints were diseased. On examination after death, it was found that the pain resulted from the implication of the obturator nerve in a mass of intrapelvic cancer, the joints themselves being perfectly sound.

TREATMENT.—The treatment must be constitutional, directed especially to re-establish a healthy condition of the uterine organs. If there be amenorrhoea and anaemia, alectics and the preparations of iron must be given; if uterine or uterine irritation or congestion exist, this must be removed by proper local means, and the general health attended to. Nervine antispasmodics and tonics, such as valerian and bark, or assafoetida and quinine in the doses should be freely administered. The most efficient treatment that can be directed to the affected joint is the application of cold douches and the employment of the continuous electric current, which will cure cases in which all other means have failed; the application of atropine and aconite may be of service to allay the pain when especially severe. If contraction or other distortion of the limb exist, the patient should be put under anaesthesia and extension or rectification of the faulty position then made, care being taken to keep the limb on splints in a proper position for some time after the operation. Indeed, in neurotic or hysterical joint affections, it is often of much use to do something positive or objective in the way of treatment, as to give the patient an excuse to get well. It is thus that free manipulation or slight "wrenching" of the joint under anaesthetics is often beneficial. In other cases the good effects following this treatment may be obtained by the stretching and restoration of the normal position of muscles which had been allowed to become contracted and displaced by long continued faulty or faulty position of the joint.

CHAPTER XLIX.

EXCISION OF JOINTS.

HISTORY.—The operation of resection of the articular ends of bones dates from the very earliest periods of surgery of which we have any record. Hippocrates, in his Chapter on Injuries of Joints, speaks of resection of bones at the joints, whether of the foot, the hand, the leg, the ankle, the forearm, the wrist, as being for the most part unattended by danger, except from syncope or consecutive fever. Celsus, in speaking of compound dislocations, says, if the bare bone project it will always be an obstacle to reduction; that which protrudes should, therefore, be cut off. Paulus Ægineta says that, if a bone projects, as after a transverse fracture, we must cut it off. Thus it will clearly be seen that it was the practice of the ancients in compound dislocations, and in compound fractures, to resect the protruding bones. But that the practice of resection in cases of disease also was not unknown to them, is evident from a passage on fistula in the works of Paulus Ægineta, who directs that, if the fistula terminate with a bone, and if that be not diseased, it should only be scraped; but if it be carious, the whole diseased portion should be cut out with chisels, and, if necessary, it may have a hole bored in it with a trephine; and a little further on he says, "the extremity of a bone near a joint, if diseased, is to be sawn off; and often, if the whole of a bone, such as the ulna, radius, tibia, or the like, be diseased, it is to be taken out entire." Nothing can probably be more explicit than this statement, in which the practice is alluded to as of frequent occurrence. But he makes exceptions in the case of the bones of the spine and pelvis, and the head of the femur, which, he says, should not be operated on for fear of the neighboring arteries.

The practice of resection thus known to and adopted by the ancients, and mentioned by the Arabian writers of the middle ages, fell completely into disuse, and seems entirely to have been forgotten until the middle of the last century, when occasional notices of its adoption appear in Surgical essays. It was first employed in cases of compound fractures and dislocations of joints. In military practice, the Surgeon, in two or three instances, picked out and cut away fragments of the bones forming the wrist, elbow, shoulder, and ankle-joints when shattered by gunshot. This early revival of resection involved no principle of treatment: imperfect operations being had recourse to on the field of battle simply as a matter of convenience in particular cases. The Surgeons who performed them did not recognize any new rule of practice as being involved in these chance procedures.

The first resection practised for injury in which the articular ends in compound dislocation were fairly, deliberately, and successfully removed, appears to have occurred to Cooper, of Bangay, before or at latest about the middle of the last century. The precise date of this case is unknown, but Cochrane writing in 1758, says that it occurred "many years ago," that the ends of both tibia and fibula were sawn off in a compound luxation of the ankle, that the limb was preserved, and was so useful that the patient was able to walk and gain his livelihood.

In or about the year 1758, Wainman, of Shripton, sawed off the lower end

of the humerus in a case of compound dislocation of the elbow-joint with perfect success, the patient recovering with an arm as movable "as if nothing had ever been amiss," and his example was shortly afterwards followed by Tyne, of Gloucester, who in a similar case removed two and a half inches of the lower end of the humerus. From this period, the operation of excision of the articular ends of bones in cases of compound dislocations and fractures soon became an established practice, and was extensively adopted by Percy in France, who, in 1794, exhibited to Sabatier nine soldiers in whom he had successfully excised the head of the humerus for gunshot injury; by Hager, in Germany, by Hey, of Leeds, and by numerous other Surgeons in this country and abroad.

The first case in which a methodical attempt at resection for disease of the articular end of a bone was made occurred to White, of Manchester, in 1768, who thus removed a large portion of the upper part of the humerus, though it is doubtful whether he actually excised the head of the bone. However this may be, he had previously satisfied himself by experiments on the dead body that this operation was practicable. Although the head of the humerus may not have been removed by White in this case, it certainly was three years later by J. Bent, of Newcastle, who in 1771 excised by a formal and prearranged operation the carious head of the humerus with complete success. His example was followed in 1778 by Orred, of Chester, who also operated successfully in a similar case. About the same time, 1775, Justamond, Surgeon to the Westminster Hospital, removed, in a case of disease of the elbow-joint, the olecranon and two inches of the ulna.

In 1762, Pirkin, of Northwich, removed the articular ends of the femur and tibia together with the patella, in a man affected with disease of the knee-joint, resulting from a fall from a horse. Pirkin was led to this operation, in consequence of having experimentally practised it on the dead subject, as a substitute for amputation of the limb, to which the patient refused to submit. The patient recovered rapidly, had a useful limb on which he was able to walk long distances, and was certainly alive nearly thirty years after the operation. This remarkable case seems to have attracted little, if any, attention, and indeed was not published until 1790, after Park, of Liverpool, brought before the Profession his second successful case of excision of the knee-joint, which occurred in 1789. That Surgeon had performed his first operation of this kind most successfully, as regarded utility of limb, in 1781, apparently without any knowledge of the operation that had been done by Pirkin nearly twenty years previously.

The example thus set by the English Surgeons was speedily followed by the Marseus in France, who, between the years 1786 and 1789, sent various memoirs to the French Academy on this subject. The operation, however, was violently opposed by the great body of Surgeons, and, with the exception of the occasional removal of the head of the humerus, fell into almost complete neglect both in this country and abroad for a period of nearly forty years, during which time the records of Surgery do not contain as many cases in which the articular ends of bones were excised for disease. It remained in this languid state until 1831, when it received a new and vigorous impulse, so far as its application to diseases of the elbow was concerned, by the publication of Syme's essay on that subject, and by the practice of Liston some years subsequently at University College Hospital.

In 1845 these operations were again prominently brought before the Profession by the performance of excision of the head of the femur by Ferguson, and although excision of the knee joint had occasionally been practised by Syme, Crumpton, Textor, Demme, Heyfelder, and others, it was not until revival in 1850 by the same accomplished Surgeon, that it came to be

extensively practised. Since that period, the operation of excision has been applied to almost every joint within reach of the Surgeon's knife.

Before proceeding to discuss the different resections in detail, we must endeavor to lay down some general rules for their performance in those cases in which alone they are admissible.

INDICATIONS FOR EXCISION.—The excision of an articulation may be practised for the following reasons:

1. As a substitute for amputation in cases in which *the joint is so extensively diseased*, that the patient will be worn out by the discharge or pain, unless it be removed. Here a useful limb may be secured by the sacrifice of the diseased part.

2. In some cases of articular disease in which *amputation would not be justifiable*, excision may be done in order to hasten the cure, and thus to save years of suffering to the patient.

3. Excision may be done in cases in which *amputation is not practicable*; as in some cases of disease of the hip-joint or of the temporo-maxillary articulation.

4. As a substitute for other and less efficient treatment, in order to *restore the utility of a limb or joint*; as in osseous ankylosis of the elbow, or in faulty ankylosis of the knee.

5. Excision may be required in *bad compound dislocations and fractures into joints*, especially in gunshot injuries; more particularly in those of the head of the humerus, and of the bones entering into the elbow-joint.

As a general rule, excisions are required only in those cases in which the articular ends of the bones are diseased either primarily or secondarily. If only the soft structures of a joint be involved, it usually happens that, without the necessity of resection or operation of any kind, a useful limb will result—in the upper extremity, with fair mobility of the articulation; in the lower, with more or less complete ankylosis, sufficient for a fair basis of support. But when the constitution is very strumous, or the bones are primarily or extensively affected, we can scarcely expect that the limb will recover to such an extent as to become useful.

In determining the necessity of excision the circumstances of the patient must be taken into consideration. Among the upper classes, who can enjoy all the advantages of good food, change of air, and careful nursing, it is rarely necessary to excise a joint, and the operation should never be undertaken till prolonged efforts have been made to obtain a cure by other means. In hospital practice, on the other hand, we have to deal with patients whose circumstances make it almost impossible for them to receive the prolonged attention essential to the recovery of a chronically diseased joint, and in them the excision may often with advantage be performed even at an early period.

CONDITIONS OF SUCCESS.—For resection to succeed, the following conditions appear to me to be necessary.

1. *The disease should not be too extensive*, so that its removal would entail such an amount of mutilation of the limb, as to render it less useful to the patient than an artificial member would be. This is especially important in the lower extremity. If the bones be so extensively affected as to require to be considerably shortened by several inches—a limb would be left, which, instead of serving as a proper basis of support to the patient, would be only a useless incumbrance. In the upper extremity, length and strength are of less consequence than in the lower; the preservation of the hand is the chief thing to aim at, and, if this be effected, the bones may be encroached on to a greater extent than is proper in the lower limb.

2. The disease for which resection is practised should be *allowed to become*

chronic before any operation is undertaken; for this there are two reasons. First, in the acute stage of disorganization of a joint, it is not always possible to say, however unpromising the case may appear, whether ankylosis may not result, so that as useful a limb would be left as could be obtained by resection. And, secondly, if the joint be excised whilst acute and active disease is going on, inflammation and diffuse suppuration of the medullary canal are liable to set in—a condition very apt to be followed by pyæmia. In the only fatal instances of resection of the elbow-joint that I have witnessed, death resulted from this cause; the operation having been performed whilst the articular affection was acute.

3. *The soft parts about the joint must be in a sufficiently healthy state.* There are two morbid conditions connected with the soft parts that may interfere with the success of resection. First, they may be so thinned and permeated by sinuses, and so adherent to the bones, that an insufficient covering would be left. Or, secondly, the long-continued existence of strumous disease in joints and bones may give rise to great infiltration of the tissues around the articulation with chronic inflammatory products often in a state of fatty degeneration or containing tubercular centres either caseating or softening. The tissues in this state are incapable of healthy repair. Chronic abscesses form, leaving sinuses when they discharge their contents, and the integuments become blue and doughy; and the soft parts around the seat of operation fall into a state of strumous disorganization, that prevents alike the formation of a false joint, osseous ankylosis, or the healing of the wound, and thus leads inevitably to the ultimate amputation of the limb. Even though this exudation-matter do not exist in large quantity, if the joint be peculiarly loose, owing to softening and disorganization of ligamentous and tendinous structures, excision is not very likely to succeed, especially in the ankle or knee.

4. *The state of the patient's constitution must necessarily influence the Surgeon materially in his determination whether to resect or to amputate.* If the constitution be tolerably sound, or even if the general health have given way as the simple consequence of pain, irritation, and continued discharge, resection will have a fair prospect of success. In fact, when the patient is hectic in consequence of continued suppuration, the removal of the joint or bone that maintains it may be advantageously practised. But if the patient is suffering from septic fever in consequence of the absorption of the discharges from ill-drained cavities opening on the surface by narrow sinuses, the operation is likely to occasion osteomyelitis and pyæmia, and is not a safe measure until the constitutional disturbance has been relieved by making free incisions, and providing good drainage. These incisions should be so placed as not to interfere with subsequent excision. Again, if the constitution appear to be very much broken down, the patient being anæmic, wasted or cachectic, especially if there be an evening elevation of temperature with no suppuration in the joint to account for it, excision of the larger joints, as the knee and hip, is not desirable, as it is very probable that the patient is suffering from general tuberculosis. If the patient be very highly strumous or decidedly phthisical, there will be little prospect of his being able to bear up through the long convalescence that often follows resection. The earlier stages of pulmonary phthisis, if unaccompanied by distinct elevation of temperature, need not be a bar to the operation. In such cases I have several times had occasion to observe that the general health improved rapidly after removal of the local disease. Extensive albuminoid degeneration of the liver and other viscera is always a serious obstacle to excision, although amputation may sometimes be safely practised.

5. *The extremity of life are unfavorable to resections.* In very early child-

hood, these operations are seldom necessary; the natural processes usually sufficing, with very little assistance, to eliminate diseased bone, and the disorganized joints admitting readily enough of ankylosis. If the disease be too severe for this, it will usually be found to be associated with so strumous a constitution as to interfere with healthy reparative action of any kind. Another serious objection to these operations in young children is that, should the epiphyses be removed, the development of the limb will be to a great extent arrested. At advanced periods of life destructive joint disease is not very common, and when it does happen, it is generally in constitutions not fitted to stand up against the prolonged drain consequent on these operations. It is at the early adult age, when the diseases most frequently occur that render resections necessary, that these operations are best borne.

REPAIR AFTER EXCISION.—The mode of repair after resection differs according to the circumstances of the operation.

When, as very commonly happens in cases of necrosis, the periosteum, thickened, infiltrated, and loosened, can readily be detached, or, indeed, is already separated, without injury to itself, from the dead bone, reproduction of new osseous tissue to a very considerable extent may be expected. My own observations on the fibula, tibia, and ulna, and those of Ollier and Maisonneuve, prove the importance of the periosteum as an organ of repair after the extraction of a dead shaft of bone from within it. Repair in this way is, I believe, chiefly to be looked for in the shafts of the long bones; although some surgeons, as Annandale, of Edinburgh, have described the os calcis as having been reproduced after subperiosteal excision. The remarkable osteogenetic properties possessed by the periosteum have been fully and conclusively established by the experiments and observations of Ollier. He has shown that a bone is much more rapidly and perfectly reproduced after removal, if the periosteum be left, than if it be removed, and he states that the osteogenetic properties of this membrane are greater in the long than in the short bones. He is of opinion also that resections performed by the subperiosteal method leave better results, so far as the shape and formation of the new joint are concerned, than if this membrane be sacrificed. These observations, indeed, conclusively establish the importance of making in all cases every effort to preserve the periosteum during the resection.

When a short bone, as the os calcis, has been entirely removed, with its periosteum attached, it is never of course regenerated, but its place is occupied by a thick, firm, fibrous cicatrix.

In some cases in which a considerable portion of the diaphysis of a long bone is taken away, repair may be imperfectly accomplished owing to sloughing of the periosteum. In a case of this kind in which two-thirds of the shaft of the humerus was lost, Macewen succeeded in obtaining complete restoration by transplantation of small fragments of bone obtained from the wedge-shaped pieces cut out of different patients for the cure of ricketsy curves in the tibia. The fragments measured about two-fifths of an inch in length and thickness, and the operation was performed with antiseptic precautions. This ingenious mode of treatment certainly deserves a further trial.

When a joint has been excised, either osseous or ligamentous ankylosis may take place or a false joint may be formed, and the surgeon should endeavor to secure the form of union most suitable to the case. Thus, when the knee has been excised, as a sound and firm limb is desirable, osseous ankylosis should, if possible, be brought about; whilst in the upper extremity mobility is of more importance than strength, and we consequently aim at obtaining firm fibrous ankylosis, allowing of some mobility at the wrist and a false joint at the elbow. In fibrous ankylosis, the opposed bony surfaces are

united to each other by dense fibrous tissue. In a false joint the ends of the bones become rounded and covered by a layer of fibroid tissue almost resembling cartilage in density and smoothness, and are united by a capsule of fibrous tissue resembling normal ligaments in structure. The inner surface of this capsule is smooth and imperfectly covered by flattened cells, and thus somewhat resembles a synovial membrane, but the cavity is moistened with serous fluid such as is found in false bursæ and not true synovia. The muscles that are naturally connected with the articular ends that have been removed form new attachments to the bones either directly or by means of the fibrous capsule of the false joint.

The question as to the arrest of the development of the bone, and consequently of the whole limb on which an operation of excision has been performed, is one of great practical moment. It is well known to physiologists that the longitudinal growth of a bone is carried on chiefly through the medium of the layer of cartilage by which the epiphysis is attached to the shaft, and which does not become ossified until the bone has attained its full length. It has further been pointed out by Humphry, that the two epiphyses of the long bones of the limbs do not take an equal share in this development, that which unites last taking the greater part. Thus the upper epiphysis in the humerus and tibia, the lower epiphysis in the radius and femur, are the more important in this respect. If, therefore, in an excision practised on a growing child, the whole of the epiphysis be removed, the subsequent growth of the bone will be arrested proportionately to the share that the epiphysis which is removed takes in the development of the bone. And if that epiphysis on which the length of the bone is chiefly dependent, be removed,—as, for instance, the upper epiphysis of the tibia and humerus, or the lower epiphysis of the thigh-bone—the development of the limb will be very considerably interfered with.

In the adult, after ossification is completed, the epiphysis loses its importance as an organ of growth; and may be removed, if necessary, without interfering with the subsequent length of the limb, except to the extent of its removal.

INSTRUMENTS.—The instruments required for resection are of a somewhat varied character: strong scalpels and bistouries, straight and sharp-pointed. In addition to these, I have found a strong-backed, probe-pointed bistoury,

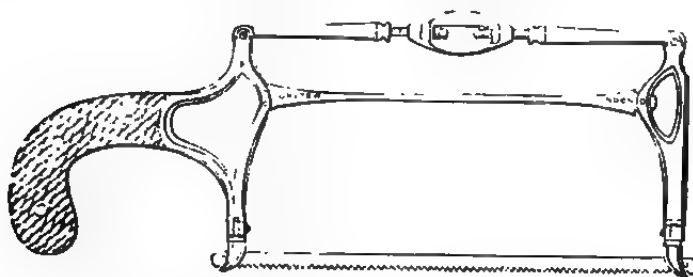

Fig. 553.—Butcher's Saw.

with a limited cutting edge, of great utility in clearing the bones. Periosteal elevators of various forms are necessary if the operation is to be performed subperiosteally. The pliers should be of various sizes and shapes (Figs. 505 to 511), and gouges will be found useful for scooping out suspicious patches on the cut osseous surfaces. For ordinary purposes, a small, broad amputating saw will be found the most convenient instrument for dividing

the bones; but in some cases a narrow keyhole saw, or that introduced by Butcher Fig. 533, will answer best. The last named instrument is especially useful when it is intended to cut the bone obliquely, or when the space is limited: for, as the blade is narrow and its angle can be changed at pleasure, any required direction can be communicated to the cut. I am at invariably use it in preference to all others in resections. But some surgeons prefer, especially in resection of the knee-joint, a short and very broad bladed saw, the blade being of breadth greater than the whole thickness of the bone to be divided. The chain-saw is, perhaps, not used as frequently as it might be.

OPERATION.—The steps of the operation must, of course, vary with the different resections; but there are some general rules that may be laid down as applicable to all cases.

1. The incisions through the soft parts should be sufficiently free to expose thoroughly the bones to be removed. By making them, as far as practicable, parallel to tendons, bloodvessels, and nerves, parts of importance may readily be avoided.

2. As little of the bone as possible should be removed. The gouge may be applied to any carious cavities or patches that appear upon the surface of the freshly cut bone; and, in this way, shortening of the bone by the saw may be materially avoided.

3. In young children the epiphysis should, if possible, not be entirely removed, as it is on the growth of this portion of bone, or rather on that of the epiphyseal cartilaginous layer adjoining the shaft, that increase in length of the bone is mainly dependent.

4. In adults in whom the bone has attained its full length, the epiphysis may be more freely removed, if necessary. But the shaft should not be encroached upon if it can be possibly avoided, and especial care should be taken not to open the medullary canal.

5. The periosteum should be carefully preserved, being stripped off the bone where it is thickened and loosened, and manipulated very gently, so that its vitality may be impaired as little as possible.

6. It is of great importance not to confound bone softened by inflammation, but otherwise healthy, or roughened by the growth of osteophytes, with that which is carious or necrosed.

7. Skin, however redundant, should seldom if ever be cut away. The flaps, at first too large, soon shrink down to a proper size, and, if trimmed, are very apt to become too scanty.

8. In cases of ordinary white swelling, the pulpy granulation-tissue occupying the site of the synovial membrane should be removed as thoroughly as possible, partly by scraping with a sharp spoon and partly by forceps and scissors.

9. After the operation, if the skin were previously unbroken, the wound may be treated by any of the antiseptic methods already described in the chapter on Wounds, the edges being brought together as accurately as possible, and proper provision made for drainage by the insertion of tubes. If sinuses exist, and the discharges are not aseptic at the time of the operation, an attempt should be made thoroughly to disinfect the wound. For this purpose, the sinuses should be scraped with a sharp spoon and afterwards syringed through with a solution of chloride of zinc (gr. xx to \bar{x} j), or tincture of iodine (ʒij to Oj). The whole wound should also be washed with the same solution, and afterwards treated by some antiseptic method. Thorough drainage and antiseptic treatment have of late years greatly diminished the death-rate of excisions in general, and especially of the knee. After the dressing is applied, the limb must be placed on a pillow or a well-padded

point, according to the joint operated on. As healing progresses, great attention must be paid to position.

10. The constitutional after-treatment should be nourishing or stimulating. As there may be a great drain on the system, should profuse suppuration set in, and a prolonged confinement to bed, the strength must be kept up under it by good diet. These operations are always serious; in many cases fully as much so as the amputation of a corresponding part, or even more so, owing to the large wound that is often inflicted in the more extensive division of the bones, to the necessity of making the incisions in the midst of diseased or injured structures, and to the more prolonged character of the after treatment.

11. Should caries or necrosis return after the operation, *secondary resection* may be required. This I have done successfully at the hip, shoulder, and elbow-joints. In the elbow, in one case, I performed a third resection with perfect success; the two previous operations, which had been performed by other and different Surgeons, having failed. The success of these secondary resections will necessarily be greatly dependent on the possibility of establishing an improved state of the patient's constitution.

EXCISIONS IN THE UPPER EXTREMITY.

The whole of the upper extremity is subservient to the hand. It is to render this more widely useful as an organ of prehension and of touch that the shoulder, the elbow, and the wrist-joints are endowed with varied and extensive movements. But the movements of each one of these joints so supplement those of the others, that any one articulation may be removed, and yet the limb be left with a sufficient range and variety of movements to render the hand useful for all the ordinary purposes of life. The limb may be shortened, and it may be weakened; and yet, if sufficient length and strength be left to enable the individual to use his hand, an immense gain will result. The limb without the hand would be a comparatively useless appendage. The hand left in its integrity is useful in a great variety of ways, however mutilated the other parts of the upper extremity may be. Hence, provided the Surgeon can save the hand, he need not hesitate to sacrifice other portions of the limb; and the shoulder, elbow, or wrist may be removed, and the patient left in the possession of a most useful and efficient member; shortened, it is true, and to a certain extent curtailed in its movements, but possessing all the delicate and intricate motions of the hand in full perfection and freedom.

SHOULDER-JOINT.—Excision of the shoulder-joint may be required for two conditions: 1. Disease, and 2. Compound and Comminuted Fracture of the Articulation.

1. **Excision for Disease.**—For disease, excision is not so commonly required in this as in many other articulations; primary disease of the soft articular structures of this joint not being very frequent, and, when it happens, usually terminating in fibrous ankylosis, without suppuration. When carious and necrosed bones are met with about the shoulder, it will frequently be found that the coracoid or acromion processes, or the scapular bone, are at fault rather than the osseous structures of the joint itself. In some cases a small sequestrum lying in a carious cavity in the head of the humerus may be removed by slitting up sinuses, without the necessity of excising the head of the bone.

When excision is required for disease of the shoulder-joint, it is usually for cases commencing in the head of the humerus, especially in children and young adults. In these cases it will be usually found that the glenoid

cavity is affected secondarily, and to so limited an extent that it readily recovers when the irritation caused by the friction of the head of the humerus against it is removed. Although in sarcomata of the upper end of the humerus excision has been practised, this operation is not usually advisable in such cases. Bickersteth has successfully removed the head of the humerus for exostosis. In cases of intra-capsular fracture through the neck of the humerus, with detachment of the head of the bone, disorganization of the joint has resulted. This has been laid open, and the loose head of the bone removed in two instances by Brainard, of Chicago; the patients recovering with useful limbs.

Operation.—Partial Excision of the head of the humerus in some cases of cancer has been practised by slitting up sinuses and the application of the gouge or sharp spoon to the diseased osseous surface. Occasionally as in cases reported by Ferguson and Sedillot, these operations have been attended by successful results. But not unfrequently they fail in effecting a cure, the disease extending, and the sinuses not healing, so that eventually excision of the whole of the diseased head of the bone has been required.

Complete Excision of the head of the humerus is the operation usually required. It may be practised in several different ways—the lines of incision through the soft parts being varied according to the conditions of the case. They are most commonly made on the front or outer side of the joint through the deltoid muscle, but in exceptional cases the head of the bone may be removed from behind. Excision may be performed by the single longitudinal or its modifications the Γ or T-shaped incision, or by a U-shaped incision or flap-operation.

The operation by the *single longitudinal incision* may be performed as follows. The patient lying on his back, with his shoulder slightly projecting over the edge of the table, the Surgeon enters the knife to the outside and above the coracoid process, about half an inch below the clavicle, and carries it directly downwards for from three to four inches, stopping immediately above the insertion of the pectoralis major. The first incision should divide the skin and fat, and pass through the anterior fibres of the deltoid, so that when the wound is held open the capsule of the shoulder-joint comes into view. This incision is immediately external to the cephalic vein, which should not be wounded, and divides no important artery or nerve. The wound being now held open with blunt hooks or copper spatula (Fig. 534), the bicipital groove should be felt for between the great and small tuberosities of the humerus. A longitudinal incision is then made firmly on to the bone along the inner side of the groove, dividing the periosteum covering the head of the bone, and the capsule as far as the margin of the glenoid cavity. If the long tendon of the biceps be still undestroyed by the disease, it must be turned out of the groove and held to the outer side in a blunt hook. The assistant then rotates the arm forcibly outwards, so as to bring the small tuberosity well into the wound, and the surgeon separates the tendon of the subscapularis and the periosteum from the bone with a periosteal elevator. In most cases of disease of the joint this can be done without great difficulty, as the adhesion of the tendon to the bone is loosened by the inflammation. Should the adhesion of the tendon be too firm to allow of its being stripped off with the elevator the knife must be used but care should be taken to shave the capsule off in such a way as, if possible, to leave it still connected with the periosteum covering the upper part of the humerus. The arm then being rotated inwards, and the limb allowed to fall over the edge of the table, the three muscles inserted into the great tuberosity are separated from the bone in the same way as the subscapularis. During this part of the operation the biceps tendon must be drawn to the inner side with a blunt hook. The

assistant then forces the head of the bone up into the wound whilst the Surgeon separates the posterior part of the capsule with an elevator, leaving it attached, if possible, to the periosteum below. He now takes the limb in his own hands, and having the soft parts well retracted he pushes the head of the bone out of the wound so as to allow the easy application of the saw by which it is removed. Should the parts around the head of the bone be thickened, and unyielding, more space may be gained by making a short cross-cut at the upper end of the longitudinal incision, and thus converting it into a modification of the Γ or T. By this method of operating, the posterior circumflex artery and the circumflex nerve are not divided, and but few vessels will be found to require ligature. The fibres of the deltoid are little interfered with, and if the incision be not carried too low, the insertion of the pectoralis major will be at most only partially cut through. It is recommended by some Surgeons to make a small opening behind through which a drainage-tube can be passed, emerging a little below the acromion. In doing this care must be taken to keep well above the posterior circumflex artery. By this means drainage is certainly facilitated, and the healing of the anterior wound is hastened.

Should the extent of the disease or injury prove to be so great as to require amputation of the limb, this may readily be done, as has been suggested by Spence, of Edinburgh, by carrying the knife round the inner side of the limb, and so detaching the member, with due attention to those points in connec-

Longitudinal Incision.

Fig. 535.—Stump after amputation at Shoulder-joint by Spence's Method.

tion with the axillary artery that have been described at p. 456, vol. i. The result, as seen by the annexed drawing (Fig. 535), is very satisfactory.

The *elliptical operation* of excision may be performed in the following way. A curved incision is made, commencing at the posterior part of the acromion, reaching downwards to the insertion of the deltoid, and terminating at the outer side of the coracoid process. By a few touches of the scalpel, a large flap composed of the deltoid muscle may thus be raised, and the diseased articulation fully exposed. As in the operation just described, an attempt should be made to save the capsule and maintain its connection with the periosteum. For this purpose a longitudinal incision should be made through the capsule, and it should be stripped off with the tendons and periosteum by means of the periosteal elevator, aided by the knife when necessary. The head being pushed out may then be removed with a narrow saw. The shaft

of the humerus should be encroached upon as little as possible, so that the arm may not be shortened more than is necessary.

After the removal of the head of the bone, the glenoid cavity must be examined. If this be merely superficially curious it may be let alone, but should it be more deeply diseased, with cavities hollowed out in it, perhaps containing sequestra, the diseased part must be removed by means of gouge-forceps and the gouge, care being taken that all diseased bone is thoroughly scooped away. After the operation, the flap must be laid down and retained in position by sutures, and a drainage-tube inserted behind.

When the sinuses open entirely behind, it is possible to excise the joint by an incision made through the posterior fibres of the deltoid, commencing immediately below the root of the acromion, and carried downwards for an inch and a half or two inches, but not so low as to endanger the circumflex nerve and artery. The space thus obtained is limited, and does not allow a methodical subperiosteal excision being performed as above described, but in most cases the capsule is softened by the disease, and the adhesions of the tendons so far loosened that there is no difficulty in forcing the head of

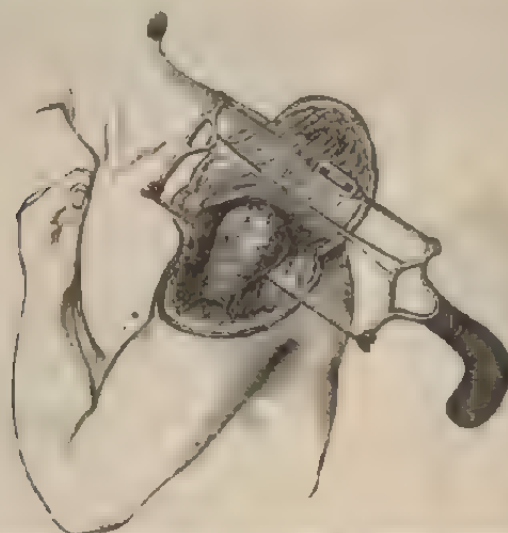

Fig. 336.—Excision of Shoulder-joint. Elliptical Incision.

the bone out of the wound. This operation was performed with the best results a few years ago by Christopher Heath in University College Hospital.

After excision of the joint, the arm must be well supported in a sling, the elbow especially being raised. A pad should be placed in the axilla to prevent the tendency of the pectoralis major, teres major, and latissimus dorsi to draw the arm inwards. The union, which is by granulation, is usually slow, and must be conducted on ordinary principles.

Result.—The shoulder-joint in its normal condition possesses five distinct movements: 1. Rotation; 2. Abduction and Elevation; 3. Adduction; 4 and 5. Movements in the antero-posterior direction. These movements vary greatly in importance in the course of the ordinary affairs of life. The most useful are those of abduction, and the two in the antero-posterior direction. These are requisite in all ordinary trades and for the guidance of the hand in most of the common occupations of life. The movements of elevation are

scissors required, except by those who follow climbing occupations, as sailors, bricklayers, etc. Now the mode of performing the operation, as well as the operation itself, will materially influence these different movements. Thus, if the deltoid be cut completely across by an elliptical incision, the power of abduction of the arm and of its elevation, will be permanently lost. If its fibres be merely split by a longitudinal incision (Fig. 354), they may be preserved or regained in great part. The movements of rotation, etc., which are dependent on the actions of the muscles that are inserted into the tuberosities of the humerus, are usually permanently lost; for in all cases of caries of the head of the humerus requiring excision, the Surgeon will find it necessary to saw through the bone below the tuberosities—in its surgical, and not in its anatomical neck. Hence the connection of the supraspinatus, infraspinatus, and teres minor, and the subscapularis to the bone will all be separated. Should the Surgeon succeed, however, in maintaining the connection of the capsule of the joint and the tendons with the periosteum by adopting the subperiosteal method of operating above described, the divided tendons may form new attachments to the humerus, and the muscles retain their functions in a greater or less degree. Those muscles which adduct and which give the antero-posterior movements, viz., the coraco-brachialis, the biceps, the pectoralis major, latissimus dorsi, and teres major, will all be preserved in their integrity, and hence it is that the arm, after this excision, is capable of guiding the hand in so great a variety of useful and unchained movements. In the case of a man whose shoulder-joint I removed many years ago, I last saw the patient about fifteen years after the operation had been performed, and then found that the upper end of the humerus had been drawn up underneath and between the acromion and coracoid processes, where a false joint had formed. The arm was extremely useful, and all the parts below the elbow were well developed. The upper arm was shortened by two and a half inches.

Excision of the shoulder-joint is on the whole a very successful operation, as regards life as well as limb. Hodges has collected 50 cases of excision of the head of the humerus for disease; of these, 8 died and 42 recovered from the operation. Of these 8 deaths, 3 only occurred before the third month, and 3 were from phthisis. In 2 only of the cases did the deaths appear to have been directly occasioned by the operation. In but 17 of these 50 cases was the glenoid cavity interfered with; but it is a remarkable circumstance that in no fewer than 7 out of the 8 fatal cases this cavity was diseased, and required either gouging, excising, or cauterization. Thus it would appear that the chance of a fatal termination is greatly increased by the implication of the glenoid cavity.

3. **Excision for Compound and Comminuted Fracture.**—When excision of the shoulder-joint is required for compound and comminuted fracture from gunshot injury, the operation is of a less formal character. The bullet-holes must be and freely open in a longitudinal direction, or the deltoid even cut across at its superior attachment, all loose splinters removed, and the ragged and comminuted ends of bone cut off with pliers or narrow saw; especial care being taken in manipulating towards the inner and under sides of the joint, in the vicinity of the plexus of nerves and large vessels. Without going back to the earlier cases of Percy, Larrey, and other military Surgeons of the latter part of the last century, who frequently practised this operation with the happiest results, the more recent experience of the wars in Europe and America demonstrated its great utility, and that it ought invariably to be preferred to amputation at the shoulder-joint in all cases in which the large blood-vessels and nerves are intact. Hodges states that in 26 recorded cases from all sources there were 25 deaths, or a mortality of 26 per cent.

But in the Crimean war the result was much more satisfactory. Tins Lindena relates 14 cases occurring in the Crimea, with only 1 death; and in the British army, of 14 cases, 12 recovered, whilst of 60 amputations at the shoulder-joint 19 were fatal. In the American war, the mortality in 77 cases of excision of the shoulder-joint was at the rate of 32 per cent. Primary excisions were more successful than secondary; the percentage of mortality in the former (252 in number) being 22.3, and in the secondary (393 in number) 38.6.

EXCISION OF THE SCAPULA, partial or complete, may be required for caries, necrosis, or tumor of that bone. Caries and necrosis do not very commonly affect the scapula primarily. When the bone becomes the seat of these diseases, it will generally be found that the acromion and the spine are the parts affected. In such cases the progress of disease is usually very slow, and it will generally be found that the carious bone may be effectually gouged out, or the sequestrum extracted, by laying open sinuses, and thus exposing the diseased osseous surface by irregular and informal operations. The whole bone has, however, become affected by necrosis, dry caries, and chronic inflammation to an incurable extent. In two instances the whole bone has been excised for disease of this kind following amputation at the shoulder-joint for caries of the humerus. The operators were Rigaud, of Strasburg, and Fergusson. Both cases did well.

The preservation of the arm after removal of the scapula is a matter of very considerable importance. The Surgeon who first ventured on the bold operation of **Removal of the Whole Scapula** was Comming, in 1808. Coctant Bey, in 1830, first amputated the arm and then proceeded to extirpate the shoulder-blade. In 1819 Liston removed the whole of the upper two-thirds of the scapula from a lad without sacrificing the arm. In 1828 Luke removed nearly the whole of the scapula from a girl of fourteen for malignant disease, sawing across the bone through its neck and the root of the acromion, and thus leaving the glenoid cavity and the acromion process. Hatman, Janson, Wutzer, and Textor have all performed similar operations removing the greater part of the bone, but leaving the glenoid cavity and more or less of the parts above the spine. In 1837 Mussey (U. S.) excised the whole of the scapula and the clavicle for an enormous osteo-sarcoma; the patient, a man, was, according to Gross, in excellent health fifteen years after this operation. In 1850 Gross removed the whole of the scapula, with the exception of the glenoid cavity, by sawing through the neck of the bone, for an osteo-sarcoma weighing seven pounds. Indeed, the American Surgeons have distinguished themselves highly in this department of surgery. Thus, in 1838, McClellan removed the whole of the scapula with the clavicle for a soft sarcoma, but the patient died. In two cases Gilbert (U. S.) removed the scapula, half of the clavicle, and the upper extremity one patient living a week, the other three months, after the operation. In 1845 Mussey successfully operated by the removal of the scapula, the outer half of the clavicle, and the upper extremity. In the case of Gross, the only portion of the scapula left attached to the upper extremity was the glenoid cavity. In 1866 Syng went a step further in this direction, and, by disarticulating the bone instead of sawing through its neck, removed the scapula with all its processes entire from a woman seventy years of age, also leaving the arm untouched. Since that period complete removal of the scapula, leaving the arm untouched, has been done several times by Syng, Jones, of Jersey, Cook, Fergusson, Pollock, Heath, and others. The arm so left becomes useful, capable of performing all the underhand movements and of lifting considerable weights; and it may now be looked upon as an established rule in surgery that it should never be removed unless it be the seat also of disease.

rendering necessary that addition to the excision of the scapula. Fergusson preferred sawing through the root of the acromion to disarticulating that process, as to give greater roundness to the shoulder and to preserve the attachment of the trapezius.

Partial Excision of the Scapula has usually been practised for tumors of that bone. The extent of bone requiring excision will necessarily vary greatly according to the size and character of the tumor, and the severity of the operation will mainly depend upon whether it is the upper or the lower portion of the bone that is the seat of disease. When the tumor is situated towards the lower angle of the bone, it may be exposed by a crucial or T-shaped incision, and the body of the bone sawn through transversely below its neck and spine. In such cases the hemorrhage need not be very great, as the main trunk of the subscapular artery, or even the dorsal artery of the scapula, is not necessarily divided. If the tumor spring from and be connected with the spine and acromion, only projecting forwards over the shoulder and leaving the rest of the bone sound, and the joint unaffected, it may be freely exposed, the spine of the scapula sawn or cut across with pliers, and the mass turned off from the point of the shoulder, without injury to the articulation or the implication of vessels of any importance.

When the tumor occupies the upper half of the scapula, the case is much more formidable, and the line of practice to be adopted must depend upon the parts involved. If the disease involve the body of the bone, encroaching upon the supra- or infraspinous fossa, extending forwards into the axilla below the neck of the scapula, and thus coming into relation with the subscapular artery, it would be wiser to remove the whole bone, than to attempt the resection of the upper half, leaving only the lower angle, which would be useless to the patient.

When the body of the scapula is involved in a morbid growth, extending over the greater part or whole of the subscapular or infraspinous region, and stretching farward under the latissimus dorsi muscle into the axilla, the case becomes infinitely more serious, as not only must the whole of the scapula be removed, but the subscapular artery must be divided, and the axillary plexus of nerves and vessels brought into the field of operation. In these cases, also, the question as to the preservation or removal of the arm has to be considered. Whenever the joint is sound, and the upper part of the limb free from disease, it should be preserved; and, as these conditions usually exist where the disease originates in the scapula, the contemporaneous or antecedent amputation of the arm is seldom required.

Operation.—Excision of the scapula may be performed by exposing the bone freely by V-shaped, T-shaped, or crucial incisions. The method most commonly adopted has been by the T-shaped incision. A long incision is made extending from the acromial end of the clavicle downwards along the anterior border of the scapula to the lower angle; from the middle or upper third of this a second incision is carried at right angles reaching to the posterior border of the bone, near the root of the spine. The flaps thus formed are dissected up and turned back, the trapezius being raised in the upper flap (if it is not implicated in the tumor). The acromio-clavicular articulation, the outer end of the clavicle, or the base of the acromion, is then cut through according to the extent of the disease. By feeling for the notch in the upper border of the scapula the situation of the suprascapular artery can be ascertained, and unless it is overlapped by the tumor it may be at once tied and divided. The posterior scapular may be now sought for by carefully dividing the levator anguli scapulae beneath which the main trunk will be found, and may be secured. An assistant can then force his finger forwards in the upper and outer angle of the wound, and compress the subclavian artery

against the first rib. The muscles attached to the posterior border may then be divided, the serratus magnus being cut as close as possible to its insertion, and the hand passed to the ventral aspect of the bone, which is thus drawn forcibly backwards and outwards. The muscles attached to the coracoid process may then be divided or the process sawn through at its root. The whole bone can now be drawn still further outwards, and the joint opened from the inner side by dividing the subscapularis close to its insertion. The disarticulation is then completed, and the remaining muscles divided, the knife being kept as close as possible to the bone so as to avoid wounding the main trunk of the subscapular. The posterior circumflex is in danger of being cut as the long head of the triceps is divided unless the edge of the knife be turned away from it. The teres major should be cut near its attachment to the scapula.

In this operation the hemorrhage is necessarily copious, and may be dangerous, but by compression of the subclavian artery after the early stages of the operation, and the immediate application of Sir Spencer Wells's forceps (a dozen of which at least should be at hand) to every bleeding point, it can usually be kept well under control. In one of the earliest cases of removal of a portion of the scapula, in which Liston took away the upper part of the bone for a vascular sarcoma, the bleeding was frightful, and was arrested only by the most energetic means.

After the operation the flaps must be laid down and retained in position by sutures, free drainage being provided by means of tubes.

Result.—In 1878 Von Adelmann published the results of 61 cases of total removal of the scapula which he had collected from medical literature. Of these, 46 recovered, 14 died, and in 1 the result was not ascertained. These cases include those in which the arm was removed at the same time as the scapula, and several in which the amputation or excision of the head of the humerus had been performed at some previous time. In 17 cases in which the subsequent utility of the arm was mentioned, it was very good in 12, in 1 only was it recorded as being very slight. In fact, the danger is much less than might at first be supposed from an operation of such magnitude.

CLAVICLE.—The clavicle may require to be partially or wholly excised. In caries or necrosis of this bone, portions of it may be gouged away or extracted without much difficulty, the bone being rarely affected through its whole thickness, and its posterior part not requiring removal; but when, in consequence of the growth of tumors, the removal of the whole or greater part of the bone is necessary, the operation is one of the most hazardous in surgery, as a glance at the anatomy of the parts lying beneath the bone, and encroached upon by the morbid growth, will indicate. In 1828 Mott excised the clavicle for an "osteosarcoma" which measured four inches in diameter. This operation was one of great difficulty; it occupied four hours in its performance, and forty ligatures were required to restrain the hemorrhage. The subclavian vein, thoracic duct, and phrenic nerve were exposed, but the patient made a good recovery, and was alive many years afterwards. Similar operations, but not perhaps of quite so formidable character, have been performed by Warren, Travers, Curtis, of Chicago, Cooper, of San Francisco, and other Surgeons. It is obviously impossible to lay down definite rules for the performance of an operation in which the circumstances must vary so greatly in each case as in this, and for the safe conduct of which the Surgeon must be indebted mainly to his anatomical knowledge. It may be stated generally that the bone requires to be exposed by a free incision along its whole length: it is then sawn across or disarticulated at its acromial articulation, and carefully dissected out in a direction from without inwards, the sternal end being forcibly twisted out, and its ligamentous connections

carefully divided, care being taken to avoid the important vessels and nerves in the lower part of the posterior triangle of the neck, and to prevent, by care before division, the entry of air into any vein which it may be necessary to divide. The sternal end only of the clavicle has been excised by Dech., of Bongay, in a case in which dislocation backwards had resulted from derangement of the spine, and the luxated end, gradually pressing upon the oesophagus, threatened the life of the patient. The bone was cut through by means of a H. V.'s saw about an inch from its sternal end, and, the acromioclavicular ligaments having been divided, the portion of bone was carefully elevated, and at last extracted.

Fig. 247. — Excision of Elbow-joint. Sawing the Humerus.

ELBOW-JOINT.—In tracing the history of the introduction of excision of the elbow-joint into surgical practice, we find, as is the case in several other parts, that it was first partially and then wholly done for injury, and proposed by one Surgeon and eventually practised by another for disease.

Thus in 1758 or 1759, Wainman, in a case of compound dislocation of the joint, sawed off the lower end of the humerus just above the fossa, leaving the patient with a flexible and useful arm. Tyne, of Gloucester, did the same, removing two and a half inches of the lower end of the humerus, in a case of compound dislocation. Justamond, of the Westminster Hospital, was the first to operate in a case of disease; this he did in 1775, removing the olecranon and two inches of the ulna. Park proposed, but did not have

an opportunity of practising, the complete extirpation of the joint. This was done for the first time by Moreau, senior, in 1794 and again by Moreau, junior, in 1797. Little was done from this time until the operation was revived by the Surgeons of Leeds; in 1818 by Stanfield, in 1819 by Chesser and Hey. It then made rapid progress in professional estimation, and was especially largely practised by Syme and Liston, and the Surgeons of the Edinburgh Infirmary. The excision of the elbow-joint has been more frequently practised than that of any other of the articulations except the knee, and the result has upon the whole been extremely satisfactory.

This operation may be required, 1, for Chronic Disease of the Joint; 2, for Osseous Ankylosis; and, 3, for Compound Fractures and Dislocations.

1. *Strumous Arthritis, or white swelling* (p. 345), is the disease for which excision of the elbow-joint is most commonly required in young subjects. It may commence either in the synovial membrane or in the bones. In this disease, the limb becomes useless, the joint is extremely painful on movement, and the surrounding soft parts are swollen, spongy, and perforated by sinuses from the openings of which fungating granulation-tissue usually projects. In older subjects the mischief will usually be found to be seated principally in the bones, and the swelling of the surrounding parts is often not great. There may be merely one or two sinuses leading down to carious or necrosed bone in the condyles or the olecranon, the joint being permanently flexed and the arm useless. On opening the joint loose pieces of dead bone may be found lying in the hollow of the olecranon, or in one of the condyles of the humerus, the rest of the articular surfaces being carious with more or less complete destruction of the articular cartilages. Most commonly, the radius is the last bone that is affected, the ulna and the articular end of the humerus being generally first diseased. In some cases excision is required on account of acute destructive arthritis secondary to suppuration taking place outside the joint and extending into it. This form forms an exception to the rule that excision of a joint is not to be undertaken while there is a hope of obtaining a cure by ankylosis. Provided the patient is otherwise healthy, the operation may be performed as soon as it is evident that the movements of the joint will be lost should recovery take place under simple treatment.

2. If *osseous ankylosis* have occurred, whether in the straight or in the bent position, excision may advantageously be practised, provided the patient is in good health. This operation was first performed in 1827, by Rhin Barton, of Philadelphia. When the elbow is ankylosed in the straight position, the arm is quite useless; and any operation by which flexion of the limb can be obtained, even without mobility of the joint, will add most materially to the patient's comfort, rendering the hand available for most purposes of life. In cases of *angular osseous ankylosis* of the elbow, a wedged-shaped piece of bone should be removed so that a useful and movable articulation may be substituted for one that is rigid and fixed.

3. In cases of *compound fracture or dislocation* of the elbow-joint, more or less complete resection of the protruding, and possibly splintered fragments, may be required (pp. 566 and 648 vol. i.).

Operation.—Excision of the elbow-joint may be performed by the **H**, the **T** shaped, or the single longitudinal incision or by two longitudinal incisions. Each method has its advocates. The **H**-shaped operation consists in making an incision parallel to, and a little to the medial side of, the ulnar nerve, another along the outer side of the joint and uniting the two by a cross-cut, dissecting up and down the two square flaps, and clearing the bones laterally. It was soon found by Surgeons that by this method a very unnecessary amount of incision was practised, and accordingly the vertical

cut along the outer side was dispensed with, and the T-shaped operation adopted. This consists in making the longitudinal incision parallel to, and a little to the radial side of the ulnar nerve, and the cross-cut over the olecranon to the outer side of the joint. Subsequent experience has shown that this incision may be still further simplified, and the operation reduced to a single longitudinal incision carried over the centre of the joint in the middle line from above downwards. In comparing these different methods of operating I decidedly give the preference to the single longitudinal incision, as being quite sufficient in all ordinary cases for the complete and easy removal of the articulation. Both the H- and T-shaped incisions involve, moreover, a complete transverse division of the tendon of the triceps, in consequence of which the power of active extension of the limb may be lost after recovery from the operation. Should the soft structures towards the outer side of the joint not yield sufficiently, a cross-cut can at once be made, so as to liberate them, and give the Surgeon more room, by turning up the two triangular flaps that will thus be formed.

The following are the successive steps of the operation by the T-shaped and single longitudinal incisions. Should the former be adopted, either in consequence of the situation of the sinuses or of previous incisions for the relief of abscesses, the arm being held across the chest, the perpendicular cut should be made parallel to, and a line or two to the outer side of, the ulnar nerve; being commenced at least two inches above the point of the olecranon, and carried down to about three inches below it. The transverse incision may then be made directly across the end of the olecranon, to the outer side of the joint, and extended as far as the extremity of the outer condyle (Fig. 538). The two triangular flaps thus made must be dissected up, the knife being carried close to the bones (Fig. 539). The subsequent steps are the same in the operation by the single longitudinal incision.

In the operation by the *single longitudinal incision* the arm is held in the position just described, and the incision is commenced from two to three inches below the tip of the olecranon and carried directly over the middle of that process, terminating a similar distance above it. If the parts are much swollen, the length of the incision must be increased so as to allow of the sides being held well apart. The incision must be carried firmly down so the bones so as completely to divide the tendon of the triceps in a longitudinal direction. The arm is then slightly extended, and soft parts cleared from the inner side of the joint. To do this the thumb must be pushed into the longitudinal cut in the triceps, and the tendon thus put on the stretch and severed away from its attachment. If the periosteum is swollen and loosened by inflammation, this may be wholly or in part done with a periosteal elevator, and the connection between the tendon and the periosteum be preserved; more commonly, however, the knife has to be used. After the triceps is separated, the remaining soft parts must be carefully turned off the inner side till the internal condyle comes into view. In doing this the edge of the knife should always be kept against the bones, or, if possible, the periosteal elevator should be used, so that the ulnar nerve may be turned over the inner condyle without injury. If the incision be properly made and the knife kept in contact with the bone, the nerve ought not to be exposed during the operation, more particularly as it is usually embedded in the inflamed tissues surrounding it. When the inner side of the joint has been sufficiently cleared the soft parts must be turned back in the same way on the outer side. In doing this it is very important to save uninjured the strong tendinous expansion that passes from the triceps over the surface of the anconeus, to be attached to the posterior border of the ulna. If this be preserved, the connection between the triceps and ulna is maintained,

and the patient will regain the power of active extension of the joint when recovery has taken place. When the posterior part of the joint has thus been laid bare, the tip of the olecranon should be removed by cutting pliers, so as to give free access to the articulation. The limb is then flexed forcibly till the forearm touches the arm, the humerus being held vertically at right angles to the table; the forearm is at the same time pulled towards the table. The lateral ligaments being then divided by a touch of the knife, the articular surface of the humerus projects from the wound, and can be removed by a narrow saw cutting from the anterior surface. If the saw inner condyle form too sharp a point, a small piece may be removed with the bone forceps. The bones of the forearm are then forced out of the wound by the assistant and cleaned with the elevator or knife till the cartilage-

Fig. 53b. — Excision of Elbow joint by shaped incision.

Fig. 54c. — Excision of Elbow joint by Longitudinal incision.

Fig. 54d. — Excision of Elbow joint by shaped incision. Ulnar Nerve exposed. Ulnar Nerve indistinctly seen.

covered surfaces are sufficiently exposed to be removed by the saw. The brachial artery is so completely protected by the brachialis anticus that it could not easily be wounded, but if there is much pulpy swelling of the synovial membrane it will sometimes be found useful to press a copper spatula between the bones to facilitate the exposure of their ends for sawing. The ulnar nerve is in danger while the inner side of the ulna is being cleaned for the saw, and sometimes during the sawing of the bone, and it must therefore be guarded or drawn on one side by a bent copper spatula or a blunt hook. Should any sinuses exist, especially towards the inner side of the arm, they had better be left untouched. I have more than once known the ulnar nerve cut across by the Surgeon in laying open what appeared to be very superficial sinuses in this situation.

In this operation it is of great consequence, so far as the after-utility of the arm is concerned, not to remove more of the bones lengthwise than is absolutely necessary. The shaft of the humerus, for instance, should never be encroached upon; it will be quite sufficient to limit the excision to the articular surface. Should any carious portions of bone extend beyond this, I think it is better to scoop them out with the gouge than to remove them in any other way. The excision of the ulna and radius should not be carried

so low as to divide the insertions of the brachialis anticus and biceps. After opening the articulation, a practical question of considerable importance often arises; viz., to what extent the resection of the articular ends should be carried. If they be all diseased, there can of course be no doubt as to the propriety of removing the ends of the three bones. So, also, if the humerus and ulna be diseased, the head of the radius should be cut off on a level with the section of the ulna. But the important point is, whether, in the event of only one bone being implicated, by disease or injury, the Surgeon should limit himself to the excision of this alone, or should remove the other two. Formerly, in accordance with the principle of conservative surgery, that diseased or injured parts alone should be sacrificed, I have advocated leaving the healthy articular ends, and only removing that which was diseased; but increasing experience has convinced me that the practice is erroneous; and that, if the joint be only partially excised, ankylosis, or return of the disease in the bones, is very apt to ensue. I would therefore advise that, in all cases, the whole of the articulation be removed, as well as in those cases in which operation is required in consequence of comminuted and compound fracture of only one of the bones; as, for instance, when the lower epiphysis of the humerus, or the upper end of the ulna only, is the seat of such injury. In excision of the elbow for faulty osseous ankylosis, a piece of the united bones about an inch in length should be sawn out: the cuts should be made at right angles to the shafts of the bones, and the piece removed must include equal portions of humerus and of ulna.

The operation by two *lateral incisions* has lately been recommended by Hueter and others. The advantages claimed for this method of operating are that it saves to some extent the injury to the triceps involved in the other methods, that it provides better drainage, and that the scars are left at the lateral aspects of the new joint instead of behind. The inner incision should be the shorter, and be made first, the ulnar nerve being turned out of its groove and the internal lateral ligament of the joint divided. The outer incision should be of considerable length, and should pass close to the radial border of the olecranon. Hueter recommends that the external lateral ligament should be divided and the head of the radius removed first. The lower end of the humerus can then be dislocated and forced out at the external wound, or sufficiently exposed to be safely sawn with a narrow-headed saw; after which the olecranon and the upper end of the ulna can be cleaned with the elevator, protruded from the wound, and removed.

In all methods of operating, it is generally recommended to save as much of the periosteum as possible. Ollier states that the results obtained by subperiosteal resection are far better than those by the older methods. In practice it will be found that, in excision for disease, whether the knife or the periosteal elevator be used, if the rule of keeping the instrument close to the bone be followed, the greater part of the periosteal covering of the bone will be saved, as its adhesion is always loosened by the inflammation. In primary excisions for injury, on the other hand, the greatest care must be taken to save the periosteum, otherwise a flail-like joint is very apt to result.

In many cases of excision of the elbow no vessels require ligature, though there may be free general oozing. I have never seen troublesome bleeding. After the operation the wound may be closed with sutures and treated according to the rules already laid down (p. 366).

Much of the success in the result of the excision of this, as of other joints, will depend upon the care and attention bestowed on the after-treatment of the case. The object of the treatment is to obtain a strong false-joint possessing all the natural movements of the elbow. In order to do this, a somewhat different course of treatment must be adopted in different cases. In

all excisions for disease, we have to guard against ankylosis; undue mobility is very rare, and I have never seen it. In primary excisions for injury, a flail-like joint is not uncommon, especially if much bone has been removed and the periosteum not preserved. I have met with it in one case—that of a young woman, the lower end of whose humerus was completely disorganized by a fall, and the elbow-joint opened. In this case the lower epiphysis of the humerus was excised, together with the articular ends of the ulna and radius.

A good recovery took place; but, although every care was taken to support the limb on splints, a very movable joint was left. In excisions for disease, or for the secondary results of wounds, we may in most cases dispense with splints. After the operation, the limb may be laid upon a pillow nearly in the extended position. Some of the Edinburgh Surgeons have recommended that the limb should be placed in the fully extended position with a very gentle weight extension applied to the wrist to prevent the bones from coming in actual contact with each other. This treatment has been tried in University College, and found to be very comfortable to the patient. At the end of a week or ten days passive movement must be commenced. In doing this, care must be taken not to grind the bony surfaces against each other, gentle extension must be maintained while the angle of the limb is altered. At first it is sufficient merely to alter the position of the limb, letting it lie in the flexed position one day and the extended the next. As the wound heals more extensive movements may be carried out daily. Pronation and supination must not be neglected, and in carrying out these movements the ulna must be held steady with one hand while the radius is rotated on it by the other hand. The pain accompanying passive movement is much less if it be commenced early than if it be delayed till fibrous union has taken place between the bones. Splints are required only if there should be any tendency to displacement immediately after operation, or if more than the usual amount of bone has been removed, or if there should be any tendency to excessive looseness of the new joint after the third week. The patient can usually leave his bed at the end of the second week, and the arm must then be carried in a sling.

In primary excisions for injury, a properly constructed splint is frequently required for some weeks, as the tendency is usually towards a flail-like, fibrous union rather than to ankylosis. A splint jointed opposite the elbow will be found useful in many cases so as to allow of variation of position when necessary. Pronation and supination must not be neglected, and must be made when the splint is removed, as no apparatus has yet been invented which will allow of these movements being carried out in a normal way whilst it is applied.

By the above mode of treatment a useful false joint can almost always be obtained. In two cases which I have had the opportunity of dissecting, one

Fig. 41.—Arm after Excision of Elbow.

sixteen months and the other two years and a half after the operation, it was found that the ends of the bones were rounded and firmly held together by a capsule of dense ligamentous tissue. In this way a most excellent and useful limb will result, having the four movements of flexion, extension, pronation, and supination nearly perfect, with but little deformity, as may be seen by the accompanying cut (Fig. 341), which was taken nearly two years after operation from a patient of mine. A coachman, whose elbow-joint I excised,

was able to drive, to lift a pail of water, and to do all the duties of his employment, nearly as well as if the arm had retained its normal condition.

Should there be any danger of ankylosis, the patient may be put under chloroform and forcible flexion and extension be employed; after which, passive motion must be kept up daily. If this fail, care must be taken that the ankylosis takes place in a flexed position.

Should recurrence of disease take place, resection may be again resorted to with success. In one case, indeed, which had been unsuccessfully operated on twice by other Surgeons, I excised the bones about the elbow for the third time with complete success, removing a considerable portion, nearly three inches, of the necrosed shaft of the humerus, and the carious upper ends of the radius and ulna. In this case, which was that of a boy about fourteen years of age, complete recovery took place. He had a most useful arm, regaining the four movements of the joint, pronation, supination, flexion, and extension, and this notwithstanding his being of a most strumous habit. Six months after the excision he was obliged to have one thigh amputated for disease of the bone, and he eventually died at the end of two and a half years, of caries of the spine.

Results.—Excision of the elbow-joint, so far as life is concerned, is a very successful operation. The result, when it is practised for compound fracture or dislocation, has been already stated at pp. 567, 648, vol. i. When practised for disease it is equally satisfactory; and indeed death can occur only from some unforeseen and accidental complication, such as may, and does occasionally follow any operation. I have lost only one patient out of very many in whom I have excised the elbow-joint. The principal danger after this operation arises from diffuse suppuration of the medullary canal of the humerus. I have seen this happen in two fatal cases in the practice of others, pyæmia developing in both instances; and in a third, in which the patient lost his life, it is probable that death, which was attributed to pneumonia, occurred from the same cause.

ULNA OR RADIUS.—One or other of the bones of the forearm has occasionally been excised with advantage, leaving a sufficiently useful limb with

Fig. 542.—Arm from which Radius has been removed.

Fig. 543.—The Radius after Removal

great power in the hand. Carnochan, of New York, and Jones, of Jersey, have successfully excised the whole ulna. In a case recorded by Weist (U. S.), nearly the whole ulna was removed on account of gunshot-wound. Care was taken to preserve as much as possible of the periosteum; and reproduction of the bone, forming a very useful limb, had taken place at the end of a year. Butts, of Virginia, has removed the whole radius. In a woman who was under my care about twenty years ago, I also resected successfully the

whole radius, with the exception of its articular head, which was removed (Fig. 543); and a useful arm, of which the annexed figure is a good representation, was left (Fig. 542). After a time the hand gradually inclines towards the radial side of the arm; but, although the articulation between it and the forearm is but a slender one through the medium of the ulna, a very useful member will be left. These operations do not require any specific rules for their performance; the bone is exposed by a long incision in the direction of, and made by sitting up, the sinuses that burrow amongst the muscles, and is then carefully dissected out from the parts amongst which it lies; especial care being taken to preserve the periosteum and any new bony deposits that may already have been formed. In one case in which the elbow-joint was involved, and the radius diseased, instead of amputating the limb I obtained an excellent result by excision of the articulation as well as of the affected bone. The patient, a builder about thirty years of age, was able, four years after the operation, to use his hand not only in all the ordinary purposes of life, but also in his trade.

The Olecranon has been successfully removed in some instances; for disease by Birckett, of Guy's Hospital; and on account of non-union after fracture by Newman, of Stamford. In each case a useful arm was retained.

WRIST.—Excision of the wrist formerly found less favor with Surgeons than the removal of other joints. The objections raised to it were, first, that in caries of the carpus the disease very often extends rapidly, with great constitutional disturbance, to all the small bones that enter into its formation, and consequently partial operations rarely succeed in curing the disease; and, secondly, that owing to the superficial character of the articulation, and its close connection with the flexor and extensor tendons, methodical operations by the older methods were almost invariably followed by a stiff and useless hand. The experience of the last twenty years has, however, shown that complete excision of the carpus with the lower ends of the bones of the forearm, and the bases of the metacarpal bones may in proper cases be undertaken with a good prospect of preserving a useful hand. I had a case in 1858, in the person of a middle-aged man in whom the whole carpus and a portion of the bases of the metacarpal bones were removed, and who recovered with a very useful hand, with some power of flexing and extending the wrist, and with very considerable mobility of the fingers. To Sir Joseph Lister, and to West, of Birmingham, however, is due the merit of proving the practicability of the operation. The mode of operating planned by the former of these Surgeons will be described here. But before giving the details of this operation, it may be well to mention the principles on which it is founded. On looking at the movements of the wrist-joint, it will be seen that they are somewhat limited in extent, so that if tolerably firm fibrous ankylosis can be obtained between the lower ends of the radius and ulna and the upper ends of the metacarpal bones, the normal amount of movement is maintained. Should these movements be lost, or should the union be so loose as to necessitate the application of a rigid apparatus to support the wrist, the hand may still be perfectly useful, the lost movement at the wrist being supplemented by those of flexion and extension at the elbow. But the hand cannot be useful if the flexion and extension of the fingers be seriously interfered with. The essential principle of Lister's operation is to save unimpaired all the tendons concerned in the movements of the thumb and fingers. If we look at the tendons that surround the wrist, we shall find them divisible into five groups: 1. Those special to the thumb; 2. The extensors of the fingers; 3. The flexors of the fingers; 4 and 5. The extensors and the flexors of the wrist. Now the incisions are so planned as to save absolutely the whole of the first three groups, and to divide only the

tendons of the wrist proper, and these are cut so close to their insertions that, as a rule, they form new attachments and resume their functions as recovery takes place.

Lister's Operation.—From the result of two cases of severe injury to the wrist-joint, which recovered with useful hands, Lister was led to the conclusion that, with proper after-treatment, the tendons about the wrist might be very freely handled without permanent stiffness resulting. At the same time, he hoped by removing the whole of the cartilaginous surfaces to be able to prevent recurrence of the disease—which is the common ending of cases of partial excision of the wrist-joint for caries of the carpus. At the time when he published his papers, he had performed the operation of excision of the wrist fifteen times. The method of operating was essentially the same in all, various small details being altered as experience suggested. The operation, as he now performs it, is done as follows: Before commencing, Esmarch's bandage and tourniquet should be applied, as without them the oozing of blood interferes considerably with the operation. Any adhesions of the tendons then existing must be forcibly broken down by moving the joints. An

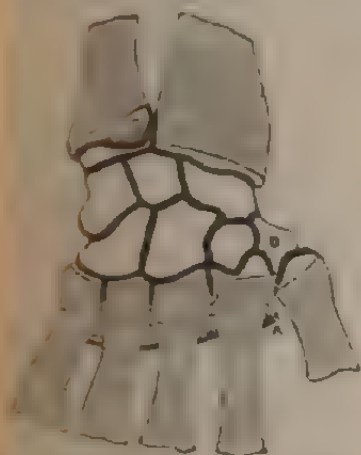

Fig. 544.—Diagram of Wrist. A Deep Palmar Arch. B Trapezium. C Articular surface of Ulna over which Extensor moves. (Lister.)

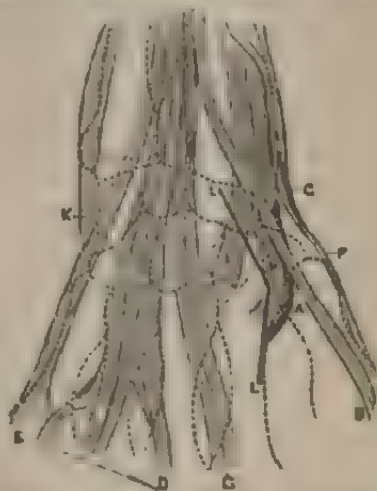

Fig. 545.—A Radial Artery. B Tendon of Extensor Secundi Internodii Pollicis. C. Extensor Indicis. D. Extensor Communis Digitorum. E. Extensor Minimi Digiti. F. Extensor Primi Internodii Pollicis. G. incision is now made "from about the middle of the dorsal aspect of the radius, on a level with the styloid process, downwards and outwards towards the inner side of the metacarpo-phalangeal articulation of the thumb; but, so reaching the line of the radial border of the metacarpal bone of the index finger, it is carried downwards longitudinally for half the length of that bone." This incision should commence in the angle formed by the tendons of the common extensor of the fingers and the extensor secundi internodii pollicis, and the upper part should run parallel to the latter tendon, but

without injuring it. The tendon of the *extensor carpi radialis brevis* will be cut, but that of the *longior* will escape for the present, and the angle formed by the two parts of the incision should be close to the inner side of its insertion. If the first part of the incision be carried too far, there is danger of wounding the radial artery. The soft parts are then to be separated carefully from the bones on the radial side of the incision, the tendon of the *extensor carpi radialis longior* being now cut as close to its insertion as possible. The tendon of the *extensor secundus internus pollicis* and the radial artery are to be pushed outwards out of the way. The trapezium must then be separated from the rest of the carpus by cutting in the longitudinal part of the incision with the bone-forceps. The soft parts on the ulnar side of the radial incision are now to be dissected up as far as can be conveniently done, the remainder being raised from the ulnar incision. While this is being done, the tendons must be relaxed by extending the joint. The trapezium is not to be removed yet, as any attempt to dissect it out before removing the rest of the carpus would endanger the radial artery and the tendon of the *flexor carpi radialis*. The ulnar incision is now to be made. It must be a free incision, commencing at least two inches above the end of the ulna and immediately to the palmar aspect of the bone, and carried directly downwards between the *flexor carpi ulnaris* and the ulna, and then straight on as far as the middle of the palmar aspect of the fifth metacarpal bone. The tendons and soft parts on the dorsum of the carpus are now to be completely raised. In doing this the tendons must be relaxed, and they are to be raised as little as possible from the radius or metacarpus. The *extensor carpi ulnaris* is to be cut as near its insertion as possible, and the dorsal and internal lateral ligaments may now be divided. Then the soft parts are to be raised from the palmar aspect. The knife must be carried close to the ulna, so as not to wound the artery and nerve. The pisiform bone is to be separated and left attached to the tendon of the *flexor carpi ulnaris*, which is not to be cut. The flexor tendons are to be raised from the metacarpal bones, but in doing this the hook of the ulniform bone must be clipped off with the bone-forceps, and care must be taken not to cut below the bases of the metacarpal bones, for fear of wounding the deep palmar arch. The tendons must be relaxed during this part of the operation by flexing the wrist. The bone-forceps may now be introduced, first between the carpus and radius, and then between the carpus and metacarpus; by this means the whole of the carpal bones (except the trapezium and the pisiform bone) are separated from their connections, and may be extracted in one mass with a large pair of sequestrum-forceps, any hands which retain them being touched with a knife.

The ends of the radius and ulna may now be easily protruded from the ulnar wound. If on examination they be found only slightly diseased, the ulna may be sawn obliquely so as to remove only its articular surface and to leave almost the whole of the styloid process. A thin slice may be taken off the end of the radius, so as just to remove only the cartilaginous surface, and its articular surface for the ulna may be removed by cutting longitudinally with the bone-forceps or a chisel. By leaving the ulna as long as possible, and by saving the styloid process, the tendency to displacement of the hand to the ulnar side is somewhat counteracted. If the bones be extensively diseased, the gouge and bone-pliers must be used freely. The next step is to expose the bases of the metacarpal bones, and to treat them in the same way as the radius and ulna, saving as much bone as possible, but removing all cartilaginous surfaces with a narrow bladed saw. The second and third are most easily protruded from the radial, and the fourth and fifth from the ulnar wound. The trapezium may then be dissected out.

being held in a strong pair of forceps. In doing this, care must be taken, first, not to wound the radial artery, which is in close relation with its outer side, and, secondly, not to cut the tendon of the flexor carpi radialis, which lies in its groove. When the trapezium is removed, the base of the metacarpal bone of the thumb may be pushed up and cut off with the bone-pliers or a small saw. It is better to remove it, as it may suffer from recurrence of the disease, and by its removal the thumb is reduced in length to the same extent as the fingers. Lastly, the pisiform bone may be examined, and either removed entirely, or its cartilaginous surface cut off, as the case requires. During the operation, the only tendons necessarily divided are the extensors of the wrist. The flexor carpi radialis may escape, from its attachment being situated low on the bases of the second and third metacarpal bones, and the flexor ulnaris is left attached to the pisiform bone. All the extensors of the thumb should be uninjured. All the tendons necessarily divided must be cut as long as possible, so that they may form new attachments in the most advantageous positions; and, in raising the flexor and extensor tendons they must be disturbed as little as possible.

After-treatment.—The radial wound may be closely united with sutures. The ulnar wound may be closed at each end, but the middle of the wound is to be kept open by means of an India-rubber drainage-tube, to allow free exit of discharge. The hand is to be placed on a splint. The most convenient is a simple wooden splint, "with an obtuse-angled piece of thick cork" stuck on it so as to maintain the hand in a state of semiflexion, with the wrist slightly extended (Fig. 546). The thumb is supported by a bar of

Fig. 546. Ulter's Splint, with Cork Support for Hand.

cork stuck on the under surface so as to project at the side (Fig. 547). The two great objects in after-treatment are to get the fingers perfectly movable and the wrist firm. For these purposes passive motion must be commenced as early as the second day in the fingers, each being bent and extended every

Fig. 547. Hand after Excision of Wrist, laid on Splint.

day fully, while the wrist is kept firmly on the splint and disturbed as little as possible during the treatment of the fingers. Special care must be taken to flex the metacarpophalangeal articulations, which are very apt to remain stiff. Pronation and supination must not be too long neglected. Passive motion must be maintained as long as there is any tendency to the formation of adhesions in the sheaths of the tendons. As the hand becomes stronger, the part of the splint supporting the fingers may be cut off. The patient must continue some support as long as he feels any weakness in the wrist.

There is often some tendency to dropping of the wrist to the ulnar side, which is best counteracted by a properly constructed gutta-percha splint. The thumb is apt to be drawn in towards the index finger; this must be prevented by a thick pad of lint kept from the earliest time between the two.

The essential points are, first, exact attention to all the details of the operation, and, next, a careful and patiently conducted after-treatment.

Results.—Since Lister described his method of operating, excision of the wrist for disease has become a recognized operation of surgery, and has been practiced successfully by West, five cases, Gillespie, and many other Surgeons. In military surgery, however, according to the statistics of the American war, the results of the operation have been far from encouraging in regard to the amount of mobility left to the hand.

HAND.—In the removal of diseased or injured portions of the hand, it is, as a general rule, of the greatest importance to sacrifice as little as possible of the unhealthy or injured structures. In all operations on the hand, indeed, we must have two great principles in view—the preservation of the utility of the member, and the maintenance, so far as practicable, of its symmetry. Utility is necessarily the primary consideration; but if a part be not useful, it may, as in the case of the head of the middle metacarpal bone in amputation of the corresponding finger, be sacrificed for the purpose of preserving the symmetry of the maimed limb. The hand is the organ of *prehension* and of *touch*; and in all operations applied to it we should endeavor, as far as practicable, to maintain its efficiency in both these respects. It is also of importance to bear in mind that two great classes of actions can be carried out by the hand—those that require force, and those that require delicacy of manipulation rather than strength. By a surgical operation we may sometimes succeed in preserving one, though we are compelled to sacrifice the other; and in this respect, our procedure should be a good deal influenced by the occupation of the patient. Thus, by partial excision, we may leave a hand that would enable a clerk to hold his pen, but which would be almost useless to a laborer or blacksmith.

In looking at the hand from a surgical point of view, we may consider it as being composed of two constituents—the hand proper, and the *Thumb*, the thumb being an accessory to the hand, and an opponent to the rest of the member, without which it is susceptible of a comparatively limited utility. Hence the thumb is of equal importance to the rest of the hand, and the preservation of its three bones is as much to be considered as that of the remaining sixteen that enter into the conformation of the metacarpals and fingers. In all cases of injury or disease implicating the thumb, every effort ought to be made for its preservation. Even if it be left stiffened and incapable of flexion, it will be a most useful opponent to the rest of the hand. Should it be found necessary to shorten it, care must be taken that as little curtailment as possible be practised: a portion of a phalanx, or its metacarpal bone even, is of essential utility in giving strength and breadth to the grasp of the hand. In cases of disease, a very useful member may be left by the removal of a portion or the whole of the ungual phalanx, of the metacarpo-phalangeal articulation or even by the excision of the metacarpal bone, the phalanges being left. These various operations are easy of performance; an incision through the diseased and disorganized soft parts will expose the necrosed bone or carpal joint, which must be removed by cutting-pliers or a narrow saw.

When the thumb has been forced back, or badly lacerated by powder flask or gun barrel explosions, it may often be saved by being replaced and maintained in position on a splint, with some form of antiseptic dressing applied

lost; and, should amputation be required, it must be done in accordance with the rule just mentioned—of saving as much as possible of the injured part.

In the conservative surgery of the **Fingers** the preservation of flexion and extension in the part left is the main thing to be aimed at; a rigid stump is always in the way. The preservation of these movements becomes more important in proportion as the palm is approached. It is of more consequence that the proximal phalanx, which carries the rest with it, should be capable of being bent into the palm, than that the distal can be flexed on the second. If the proximal phalanx can be bent down, a very small degree of movement in the distal one will be sufficient to furnish pliability enough in the finger to make it a useful member; but if the proximal one be stiffened, no amount of mobility in the distal phalanx can make it useful.

In preserving these movements, it is necessary to be particularly careful of the sheaths of the tendons. If they be in any way opened or injured, it will generally be found either that the tendon sloughs, or that it becomes adherent to its sheath in such a way that all movement is lost, or at least greatly impaired.

The only phalanx that can be excised with advantage is the distal one. It often happens, in the destructive disorganization which results from whitlow, that this necroses; when, instead of amputating the end of the finger, it may be removed by an incision on its palmar aspect. Disease of the phalangeal articulations usually leads to amputation of the affected finger. The rules for performing these various operations have already been laid down at pp. 114 *et seq.*, vol. i., to which I must refer the reader.

Resection of the **Metacarpal Bone**, either of the thumb or index finger, without the removal of the corresponding digit, is occasionally required, more particularly in cases of injury; it may readily be done by making a longitudinal incision over the dorsal aspect of the bone to be removed, carefully detaching it from surrounding parts by keeping the edge of the knife close against the bone, avoiding the tendons, and then either disarticulating, or (what is preferable) cutting across the neck of the carpal end of the bone, turning it out, and separating it from any distal attachments which it may retain. After the removal of the metacarpal bone of the index finger in this way, but little deformity results, and a very useful hand will be left, more particularly in children, on whom I have more than once had occasion to practise this partial resection with success. If the periosteum be saved, the bone may be to some extent reproduced, but in order to obtain this result it is necessary to keep the finger drawn forwards by an elastic extending apparatus, to prevent the first phalanx from being pulled back on to the carpus by the muscles attached to it.

CONSERVATIVE SURGERY OF THE LOWER EXTREMITY.

In all conservative operations that are practised on the lower extremity, it is of essential importance that a good basis of support, of sufficient length and stamity be left to the body. These operations differ thus in some important respects from those that are practised on the upper extremity. In the latter the preservation of the hand, even though in a mutilated condition is the thing at which the surgeon aims; and, provided this be attained, it matters comparatively little how much the arm may be shortened or impaired in power. In the lower extremity, however, strength, length, and stamity are essential to the patient's comfort and utility, and unless these can be secured, his interests are better served by the removal of the limb, and the adaptation of some artificial contrivance, than by leaving a

shortened, wasted, and crippled member, which is unequal to support the weight of the body.

HIP-JOINT.—Excision of the head of the thigh bone has of late years been a good deal practised in some cases of hip-joint disease. This operation may, however, most conveniently be considered in connection with that affection (Chapter LII).

KNEE.—Excision of the knee-joint was originally performed at the close of the last century by Park, Wilkin, and the Moreaus, but it fell into disfavor until it was revived in 1840 by Fergusson, since which time it has been exten-

Fig. 348. Thomas's Knee-splint.

Fig. 349. Thomas's Knee-splint Applied.

sively practised. During the last few years, since the operation has been relieved of many of its dangers by the improved methods of treating wounds, it has been performed more frequently than ever, and with steadily improving results.

Excision of the knee is undertaken in the great majority of cases for white swelling of the joint, but Surgeons differ considerably as to the period at which the operation should be performed. All are agreed that among the upper and middle classes, and in country practice, it should be employed only as a last resource, as a substitute for amputation, when all other means have failed to cure the disease. On the other hand, many Surgeons have become so disheartened with repeated failures to cure white swelling of the knee in the children of the poor of large cities, that they have resorted to

decision at a very early period. It is not wise, however, to adopt a uniform mode of treatment for all cases; each should be judged on its own merits.

The treatment of a case of white swelling of the knee should be conducted on the principles already laid down (p. 352); but a brief sketch of the points having special reference to this joint may not be out of place here. From the earliest stage, perfect rest of the joint is essential; without this there is no hope of cure. This may be obtained by the application of some rigid apparatus, as the plaster-of-Paris or starched bandage, reaching from the fold of the nates to the toes, the patient being allowed to move about on crutches, without putting the foot to the ground. The most efficient apparatus is, however, the simple and ingenious splint, invented by H. O. Thomas, of Liverpool (Figs. 548, 549). Besides giving the most perfect rest, this has the great advantage of leaving the joint exposed so that the effects of the treatment can be observed, and, at the same time, it enables the patient to move about, as in Fig. 549. The apparatus consists of a well-padded iron ring, covered with leather, from which an iron rod extends downwards on each side of the leg, terminating in a second ring at the lower end. Attached to one of the iron rods is a piece of soft leather, which, when the splint is applied, may be brought up behind the limb, and secured to the other rod by being laced over it and fixed with strong pins. This leather is not essential, and in many cases the limb can be better fixed without it. The foot-piece represented in Figs. 548, 549, is required only when the splint is used to fix the limb after excision of the joint; in other cases it is not only useless, but injurious. In ordinary cases in which the limb is tolerably straight, the apparatus is thus applied: The splint must be of such a length as to extend from three to four inches beyond the foot. Two strips of strong strapping are prepared of sufficient length to reach from immediately below the head of the tibia to one inch beyond the sole of the foot; to one end of each of these a stout tape is firmly sewn. The strips are then applied to the sides of the leg, the tapes being below. To give additional security, some narrower strips must be wound spirally round the leg, care being taken not to apply them circularly, or with sufficient tightness to constrict the limb. Over all, a flannel bandage may be applied from the ankle to the upper end of the thigh. The strips of plaster thus applied, if of proper quality, should retain their hold without shifting for many weeks. The limb is then passed through the upper ring of the splint, which is pushed upwards till it gets a firm bearing against the tuberosity of the ischium. The splint is then secured in position by tying the tapes attached to the strips of plaster to the ring at the bottom of the splint. It is not intended in so doing forcibly to extend the limb, but merely to retain the splint steadily in position. If the patient is to walk on the splint, it is better to have a bar fixed across between the two vertical rods, about one inch above their lower ends to which the tapes can be made fast, otherwise they are quickly worn through. The limb being thus fixed longitudinally, lateral and antero-posterior movements are prevented by two broad strips of plaster, about three feet long and three to five inches wide, one to be applied to the middle of the thigh, and the other to the leg opposite the calf. The strip of plaster is first fixed to one of the lateral rods, then brought over or under the limb, and back to the same bar, the remainder of the strip being wound round, including both bars and the limb. The second strip is then applied in the same way, but is fixed to the opposite lateral rod. A broad strip of bandage or plaster is then applied behind the knee between the two lateral rods, so as to support the ham. This is not necessary if the leather is fixed to the splint, as in Fig. 548. Lastly, a flannel bandage is smoothly applied from the toes to the groin. If properly put up, the apparatus should not require changing for some weeks; the tapes may

without injuring it. The tendon of the *extensor carpi radialis brevior* will be cut, but that of the *longior* will escape for the present, and the angle formed by the two parts of the incision should be close to the inner side of its insertion. If the first part of the incision be carried too far, there is danger of wounding the radial artery. The soft parts are then to be separated carefully from the bones on the radial side of the incision, the tendon of the *extensor carpi radialis longior* being now cut as close to its insertion as possible. The tendon of the *extensor secundi internodii pollicis* and the radial artery are to be pushed outwards out of the way. The trapezium must then be separated from the rest of the carpus by cutting in the longitudinal part of the incision with the bone-forceps. The soft parts on the ulnar side of the radial incision are now to be dissected up as far as can be conveniently done, the remainder being raised from the ulnar incision. While this is being done, the tendons must be relaxed by extending the joint. The trapezium is not to be removed yet, as any attempt to dissect it out before removing the rest of the carpus would endanger the radial artery and the tendon of the *flexor carpi radialis*. The ulnar incision is now to be made. It must be a free incision, commencing at least two inches above the end of the ulna and immediately to the palmar aspect of the bone, and carried directly downwards between the *flexor carpi ulnaris* and the ulna, and then straight on as far as the middle of the palmar aspect of the fifth metacarpal bone. The tendons and soft parts on the dorsum of the carpus are now to be completely raised. In doing this the tendons must be relaxed, and they are to be raised as little as possible from the radius or metacarpus. The *extensor carpi ulnaris* is to be cut as near its insertion as possible, and the dorsal and internal lateral ligaments may now be divided. Then the soft parts are to be raised from the palmar aspect. The knife must be carried close to the ulna, so as not to wound the artery and nerve. The pisiform bone is to be separated and left attached to the tendon of the *flexor carpi ulnaris*, which is not to be cut. The flexor tendons are to be raised from the metacarpal bones, but in doing this the hook of the ulnariform bone must be clipped off with the bone-forceps, and care must be taken not to cut below the bases of the metacarpal bones, for fear of wounding the deep palmar arch. The tendons must be relaxed during this part of the operation by flexing the wrist. The bone-forceps may now be introduced, first between the carpus and radius, and then between the carpus and metacarpus; by this means the whole of the carpal bones (except the trapezium and the pisiform bone) are separated from their connections, and may be extracted in one mass with a large pair of sequestrum-forceps, any bands which retain them being touched with a knife.

The ends of the radius and ulna may now be easily protruded from the ulnar wound. If on examination they be found only slightly diseased, the ulna may be sawn obliquely so as to remove only its articular surface and to leave almost the whole of the styloid process. A thin slice may be taken off the end of the radius, so as just to remove only the cartilaginous surface; and its articular surface for the ulna may be removed by cutting longitudinally with the bone-forceps or a chisel. By leaving the ulna as long as possible, and by saving the styloid process, the tendency to displacement of the hand to the ulnar side is somewhat counteracted. If the bones be extensively diseased, the gouge and bone-pliers must be used freely. The next step is to expose the bases of the metacarpal bones, and to treat them in the same way as the radius and ulna, saving as much bone as possible, but removing all cartilaginous surfaces with a narrow-bladed saw. The second and third are most easily protruded from the radial, and the fourth and fifth from the ulnar wound. The trapezium may then be dissected out,

limb resulting from old disease or injury, by which the limb has been rendered useless.

Operation.—Excision of the knee-joint may be performed by making a horseshoe incision with the convexity downwards, commencing at the side of one condyle of the femur, and passing immediately above the tubercle of the tibia to a corresponding point on the opposite condyle (Fig. 550). By this

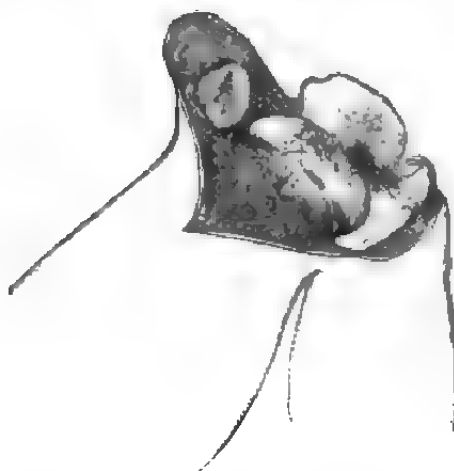

Fig. 550.—Elliptical Incision in Excision of the Knee-joint

incision the ligamentum patellæ is divided, and the patella turned up in the elliptical flap; the crucial ligaments, if not already disorganized, are then to be cut across, any remaining lateral attachments divided, and the bones cleared for the saw. In doing this the limb must be forcibly flexed, and the knife carefully applied to the posterior part of the head of the tibia; for this purpose a blunt-pointed resection-knife is the best. The articular surfaces must now be sawn off. This may be done with Butcher's saw; but in order to insure a perfectly smooth section of the bones, many Surgeons prefer to use a common saw, somewhat broader than that ordinarily employed in amputations. The lower end of the thigh-bone should first be removed. The saw-cut may safely be carried from before, backwards, or in the opposite direction, as there is no danger of injuring the popliteal vessels. It must be made accurately at right angles to the shaft of the femur, in the antero-posterior direction; but, in the transverse, it should be parallel to the articular surface, that is to say, the inner side must be left slightly the longer, as the internal condyle is naturally longer than the outer. If the condyles retain their normal shape it is not difficult to judge the proper angle at which the saw should be held; but if they are extensively and irregularly destroyed, the following guide may be taken. The patient lying flat on his back, the thigh is flexed to a right angle, and adducted till the inner side of the knee corresponds to the middle line of the body; the saw is then to be held parallel to the surface of the table. A thin slice is next taken off the tibia. It is usually recommended to cut from behind forwards (Fig. 551) to avoid wounding the popliteal vessels; but if ordinary care be taken, there is no risk of doing this, and it is more convenient to saw in the opposite direction. The section must be accurately at right angles to the shaft of the tibia in both directions.

It has been recommended to saw the tibia concave and the femur convex,

using a Butcher's saw, but it is difficult to do this so that the bones shall fit accurately, and the method presents no advantage over the ordinary way of operating. Care must be taken not to remove more of the bones than is absolutely necessary, especially in young subjects, lest the epiphyses be completely removed, and the growth of the limb interfered with. It is usually sufficient to remove from one-third to three-fourths of an inch of the tibia and about one inch or an inch and a half of the thigh-bone (Figs. 552 and 553). In young children the ends of the bones can sometimes be shaved off with a knife, and the amount taken away accurately limited to the diseased tissue. It not unfrequently happens that carious cavities are found extending below

Fig. 551.—Application of Butcher's Saw to Head of Tibia.

Fig. 552.—Lower End of Femur excised.

Fig. 553.—Upper End of Tibia excised.

the level of the section that has been made; when this is the case, it is better to apply the gouge to them than to saw the bone below their level. Should the operation be performed for deformity consequent upon badly reduced fractures or dislocations about the knee, as has been done successfully by Humphry, of Cambridge, it may be necessary, in order to bring the limb into good position, to remove a wedge-shaped piece from one of the bones.

If the patella be much diseased, it must be removed; if it be only slightly carious, it may be scraped or gouged out; and, if healthy, in accordance with that principle of conservative surgery by which no sound part is removed, it should be left, becoming consolidated with and strengthening the joint. The articular surface of the patella on the thigh bone, which extends some way up its forepart, may advantageously be sliced off, so as to leave an osseous surface, instead of a cartilaginous one, for the attachment of the patella.

I have always found the operation, as it has just been described, easy of performance and good in its results; but various modifications are adopted by different Surgeons. Thus, some make one straight transverse incision; others two parallel incisions, one on each side of the patella, or an H shaped incision, and thus open the articulation from the side. Jones, of Jersey, who had great experience in this operation, advised that the skin be dissected up by means of a semilunar incision, and then that the ligamentum

patella be preserved by being pushed with the patella and the quadriceps extensor tendon to one side, the joint then opened, and the bones sawn. Others advise that the patella be always removed. Volkmann recommends a straight incision, passing from one condyle of the femur to the other transversely across the middle of the patella, which is then sawn through so as to expose the joint. After the articular ends of the femur and tibia have been removed, the fragments of the patella are united to each other by sutures of catgut, carbolized silk, or wire. If its articular surface is diseased, it must be sliced off or scraped. The results obtained by this method are very good; the patella readily unites by bone, and either remains movable or becomes fixed to the femur. The attachment of the quadriceps extensor and ligamentum patellæ being undisturbed, the tendency to displacement of the tibia backwards after the operation is counteracted, and in walking the action of the rectus in bringing the limb forwards is preserved.

Dr Davy, of the Westminster Hospital, has very ingeniously and successfully modified the operation of excision of the knee-joint by uniting the bones on the "Tenon and Mortice" principle, thus securing more solid bony ankylosis. He cuts the end of the femur into a wedge-shape, constituting the tenon, and cuts out a mortice in the upper end of the tibia, into which the wedge-shaped end of the femur is driven, and maintained with absolute fixity by means of a wire splint with foot-piece. This is disturbed as little as possible until firm union is established.

After the ends of the bones have been removed, in cases of white swelling, the pulpy granulation-tissue representing the synovial membrane must be cleaned away as completely as possible, partly by scraping with a sharp spoon and partly by the use of scissors and forceps. Some caution is necessary in cleaning the posterior part of the joint to avoid wounding the popliteal vessels. The healing of the wound is much facilitated and the subsequent suppuration diminished by this proceeding. If sinuses existed before the operation, they may be scraped and cleaned with a solution of carbonate of zinc.

In order to keep the bones in position, some Surgeons drill them obliquely at the anterior part and secure them by a couple of strong sutures of catgut, carbolized silk, or wire. Strong catgut answers the purpose very well, and will not soften for about two weeks, after which time it is no longer needed. If the wound is not aseptic, wire sutures are the best, if any be used.

It is very important that all hemorrhage should be thoroughly arrested before the wound is closed. In some cases no ligatures will be required, but usually two or three of the articular arteries furnish sufficient hemorrhage to require restraint. The flap when laid down will often appear inconveniently long and thick, but it must not be curtailed, as it will eventually contract and fit well. As a rule, drainage-tubes are not necessary, and the flap, having no tendency to become displaced, only requires a few sutures to hold it in position.

The result of the operation will depend mainly on the care taken in the after-treatment, and in the successful prevention of decomposition in the discharges. It is essential for success that the limb should be kept at perfect rest for the first few weeks; any apparatus, therefore, which requires complete removal for dressing the wound should be avoided. A narrow splint of padded iron, extending from the buttock to the heel, will usually answer the purpose sufficiently well. It must be padded where it is in contact with the thigh and the calf to such an extent that it is not in actual contact with the skin in the ham. It must be fixed in position by a flannel-bandage above and below the knee, over which a firm plaster-of-Paris bandage must be

There is often some tendency to dropping of the wrist to the ulnar side, which is best counteracted by a properly constructed gutta-serena splint. The thumb is apt to be drawn in towards the index finger; this must be prevented by a thick pad of lint kept from the earliest time between the two.

The essential points are, first, exact attention to all the details of the operation, and, next, a careful and patiently conducted after-treatment.

Results.—Since Lister described his method of operating, excision of the wrist for disease has become a recognized operation of Surgery, and has been practised successfully by West, five cases, Gillespie, and many other Surgeons. In military surgery, however, according to the statistics of the American war, the results of the operation have been far from encouraging in regard to the amount of mobility left to the hand.

HAND.—In the removal of diseased or injured portions of the hand, it is, as a general rule, of the greatest importance to sacrifice as little as possible of the unhealthy or injured structures. In all operations on the hand, indeed, we must have two great principles in view—the preservation of the utility of the member, and the maintenance, so far as practicable, of its symmetry. Utility is necessarily the primary consideration; but, if a part be not useful, it may, as in the case of the head of the middle metacarpal bone in amputation of the corresponding finger, be sacrificed for the purpose of preserving the symmetry of the maimed limb. The hand is the organ of *prehension* and of *touch*; and in all operations applied to it we should endeavor, as far as practicable, to maintain its efficiency in both these respects. It is also of importance to bear in mind that two great classes of actions can be carried out by the hand—those that require force, and those that require delicacy of manipulation rather than strength. By a surgical operation we may sometimes succeed in preserving one, though we are compelled to sacrifice the other; and in this respect, our procedure should be a good deal influenced by the occupation of the patient. Thus, by partial excision, we may leave a hand that would enable a clerk to hold his pen, but which would be almost useless to a laborer or blacksmith.

In looking at the hand from a surgical point of view, we may consider it as being composed of two constituents—the hand proper, and the *Thumb*, the thumb being an accessory to the hand, and an opponent to the rest of the member, without which it is susceptible of a comparatively limited utility. Hence the thumb is of equal importance to the rest of the hand; and the preservation of its three bones is as much to be considered as that of the remaining sixteen that enter into the conformation of the metacarpus and fingers. In all cases of injury or disease implicating the thumb, every effort ought to be made for its preservation. Even if it be left stiffened and incapable of flexion, it will be a most useful opponent to the rest of the hand. Should it be found necessary to shorten it, care must be taken that as little curtailment as possible be practised; a portion of a phalanx, or its metacarpal base even, is of essential utility in giving strength and breadth to the grasp of the hand. In cases of disease, a very useful member may be left by the removal of a portion or the whole of the ungual phalanx of the metacarpo-phalangeal articulation or even by the excision of the metacarpal bone, the phalanges being left. These various operations are easy of performance, an incision through the diseased and disorganized soft parts will expose the necrosed bone or carious joint, which must be removed by cutting-pliers or a narrow saw.

When the thumb has been forced back, or badly lacerated by powder flask or gun barrel explosions, it may often be saved by being repinned and maintained in position on a splint, with some form of antiseptic dressing applied

best, and, should amputation be required, it must be done in accordance with the rule just mentioned—of saving as much as possible of the injured part.

In the conservative surgery of the **Fingers** the preservation of flexion and extension in the part left is the main thing to be aimed at; a rigid stump is always in the way. The preservation of these movements becomes more important in proportion as the palm is approached. It is of more consequence that the proximal phalanx, which carries the rest with it, should be capable of being bent into the palm, than that the distal can be flexed on the second. If the proximal phalanx can be bent down, a very small degree of movement in the distal one will be sufficient to furnish pliability enough in the finger to make it a useful member; but if the proximal one be stiffened, no amount of mobility in the distal phalanx can make it useful.

In preserving these movements, it is necessary to be particularly careful of the sheaths of the tendons. If they be in any way opened or injured, it will generally be found either that the tendon sloughs, or that it becomes adherent to its sheath in such a way that all movement is lost, or at least greatly impaired.

The only phalanx that can be excised with advantage is the distal one. It often happens, in the destructive disorganization which results from whitlow, that this necroses, when, instead of amputating the end of the finger, it may be removed by an incision on its palmar aspect. Disease of the phalangeal articulations usually leads to amputation of the affected finger. The rules for performing these various operations have already been laid down at pp. 114 *et seq.*, vol. ii, to which I must refer the reader.

Resection of the **Metacarpal Bone**, either of the thumb or index finger, without the removal of the corresponding digit, is occasionally required, more particularly in cases of injury; it may readily be done by making a longitudinal incision over the dorsal aspect of the bone to be removed, carefully detaching it from surrounding parts by keeping the edge of the knife close against the bone, avoiding the tendons, and then either disarticulating, or (what is preferable) cutting across the neck of the carpal end of the bone, turning it out, and separating it from any distal attachments which it may retain. After the removal of the metacarpal bone of the index finger in this way, but little deformity results, and a very useful hand will be left, more particularly in children, on whom I have more than once had occasion to practise this partial resection with success. If the periosteum be saved, the bone may be to some extent reproduced, but in order to obtain this result it is necessary to keep the finger drawn forwards by an elastic extending apparatus, to prevent the first phalanx from being pulled back on to the carpus by the muscles attached to it.

CONSERVATIVE SURGERY OF THE LOWER EXTREMITY.

In all conservative operations that are practised on the lower extremity, it is of essential importance that a good basis of support, of sufficient length and sturdiness, be left to the body. These operations differ thus in some important respects from those that are practised on the upper extremity. In the latter, the preservation of the hand, even though in a mutilated condition, is the thing at which the surgeon aims; and, provided this be attained, it matters comparatively little how much the arm may be shortened or impaired in power. In the lower extremity, however, strength, length, and solidity are essential to the patient's comfort and utility, and unless these can be secured, his interests are better served by the removal of the limb, and the adaptation of some artificial contrivance, than by leaving a

shortened, wasted, and crippled member, which is unequal to the weight of the body.

HIP-JOINT.—Excision of the head of the thigh-bone has of late been a good deal practised in some cases of hip-joint disease. It may, however, most conveniently be considered in connection with the next affection (Chapter LII.).

KNEE.—Excision of the knee-joint was originally performed of the last century by Park, Filkin, and the Moreaus, but it fell into disrepute until it was revived in 1850 by Fergusson, since which time it

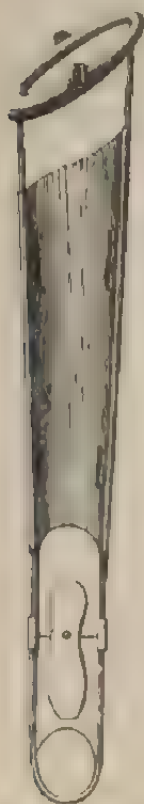

Fig. 548.—Thomas's Knee-splint.

has been extensively practised. During the last fifty years it has been robbed of many of its dangers by the fact that it has been performed more frequently and with better results.

Excision of the knee is undertaken only when the swelling of the joint, but Surgeon General has recommended which the operation should be performed in the upper and middle classes, and only as a last resource, as a substitute for amputation. It has been found to have failed to cure the disease in many cases, and to become so disheartened with the results that it has been abandoned in the children of the

y longer than the outer. If the condyles retain their nor-
t difficult to judge the proper angle at which the saw should

be tightened if they become loose, and the flannel bandage reapplied daily, but the strapping should not be touched. In walking, a patten is worn on the foot of the sound side, so as to equalize the length of the two limbs (Fig. 549). A broad strap may be carried from the splint over the opposite shoulder, as in Fig. 549, but if the extension apparatus is properly fixed to the leg, and the tapes tied sufficiently tightly, this is not necessary. A Thomas's splint applied as above described is perhaps the most perfect apparatus ever invented for fixing the knee. If, however, all the details are not attended to, it becomes as useless as any other form of splint. Even if the limb is flexed to a considerable angle, the Thomas's splint may be applied as above described, slight modifications being made to suit the altered position of the limb. After a few weeks in bed the limb will usually become straight, if no ankylosis exists.

During the time that the limb is on the splint the accessory means of treatment, such as counter-irritation or pressure by an elastic bandage, may be employed, should they be considered necessary; but in a large proportion of cases simple rest is all that is required. If the joint improves under this treatment, it must be patiently continued for many months, or even a year or more. Should the joint continue to enlarge, and abscesses form in spite of the treatment, or should the case be seen for the first time after these complications have arisen, operative interference is required. It is not necessary, however, to have immediate recourse to excision or amputation. If the general health of the patient is good, and his surroundings favorable, an attempt may be made to save the ends of the bones by making free incisions along the lateral aspects of the joint as far back as possible, so as to drain the cavity thoroughly. If they are made too near the patella, a pouch is left behind the incision on each side, in which the discharges may accumulate. The incisions should extend from the level of the upper limit of the pouch of synovial membrane above the patella to the head of the tibia. If an abscess be found burrowing beyond this point, the knife must be carried further, so as to lay it freely open. The incisions having been made, the pulpy granulation-tissue filling the cavity of the joint may be freely scraped away with a sharp spoon, and if a carious patch be felt on either of the bones this also may be treated in the same way. In some cases sequestra may be found, and removed. By this mode of treatment good results have been obtained by H. O. Thomas and Rushton Parker, of Liverpool. It is specially adapted to children under fourteen or fifteen years of age, and the younger the child the better hope there is of success. In adults it is rarely to be recommended, nor is it practicable when the bones are extensively destroyed. The operation should be performed with the strictest antiseptic precautions. In the after-treatment drainage-tubes are not necessary if the incisions are sufficiently free. The dressing must be changed at the end of the first twenty-four hours, as it will be soaked by the abundant bloody and serous discharge which flows away immediately after the operation. An antiseptic cotton-wool dressing, either of iodoform or salicylic wool, may then be applied, enveloping the knee wholly on each side, and surrounding the splint. This may be left undisturbed till some discharge soaks out, unless severe pain or elevation of temperature indicate that all is not going on well. König strongly recommends the application of some iodoform to the inside of the joint at the operation. Should the treatment fail to arrest the disease, the incisions can be utilized in a subsequent excision or amputation.

When the foregoing methods fail, or in cases not adapted to the treatment by incision, excision of the joint or amputation becomes necessary to save the life of the patient.

Excision of the knee-joint may be practised also in cases of faulty anky-

limb resulting from old disease or injury, by which the limb has been rendered useless.

Operation.—Excision of the knee-joint may be performed by making a horizontal incision with the convexity downwards, commencing at the side of one condyle of the femur, and passing immediately above the tubercle of the tibia to a corresponding point on the opposite condyle (Fig. 550). By this

Fig. 550.—Elliptical Incision in Excision of the Knee joint

incision the ligamentum patellæ is divided, and the patella turned up in the elliptical flap; the crucial ligaments, if not already disorganized, are then to be cut across, any remaining lateral attachments divided, and the bones cleared for the saw. In doing this the limb must be forcibly flexed, and the knife carefully applied to the posterior part of the head of the tibia; for this purpose a blunt-pointed resection-knife is the best. The articular surfaces must now be sawn off. This may be done with Butcher's saw; but in order to insure a perfectly smooth section of the bones, many Surgeons prefer to use a common saw, somewhat broader than that ordinarily employed in amputations. The lower end of the thigh-bone should first be removed. The saw-cut may safely be carried from before, backwards, or in the opposite direction, as there is no danger of injuring the popliteal vessels. It must be made accurately at right angles to the shaft of the femur, in the antero-posterior direction; but, in the transverse, it should be parallel to the articular surface, that is to say, the inner side must be left slightly the longer, as the internal condyle is naturally longer than the outer. If the condyles retain their normal shape it is not difficult to judge the proper angle at which the saw should be held; but if they are extensively and irregularly destroyed, the following guide may be taken. The patient lying flat on his back, the thigh is flexed to a right angle, and adducted till the inner side of the knee corresponds to the middle line of the body; the saw is then to be held parallel to the surface of the table. A thin slice is next taken off the tibia. It is usually recommended to cut from behind forwards (Fig. 551) to avoid wounding the popliteal vessels; but if ordinary care be taken, there is no risk of doing this, and it is more convenient to saw in the opposite direction. The section must be accurately at right angles to the shaft of the tibia in both directions.

It has been recommended to saw the tibia concave and the femur convex,

using a Butcher's saw, but it is difficult to do this so that the bones shall fit accurately, and the method presents no advantage over the ordinary way of operating. Care must be taken not to remove more of the bone than is absolutely necessary, especially in young subjects, lest the epiphyses be completely removed, and the growth of the limb interfered with. It is usually sufficient to remove from one third to three-fourths of an inch of the tibia, and about one inch or an inch and a half of the thigh-bone. Figs. 552 and 553. In young children the ends of the bones can sometimes be sliced off with a knife, and the amount taken away accurately limited to the diseased tissues. It not unfrequently happens that carious cavities are found extending below

Fig. 551.—Application of Butcher's Saw to Head of Tibia.

Fig. 552.—Lower End of Femur, excised.

Fig. 553.—Upper End of Tibia, excised.

the level of the section that has been made; when this is the case, it is better to apply the gouge to them than to saw the bone below their level. Should the operation be performed for deformity consequent upon badly reduced fractures or dislocations about the knee, as has been done successfully by Humphry, of Cambridge, it may be necessary, in order to bring the limb into good position, to remove a wedge-shaped piece from one of the bones.

If the patella be much diseased, it must be removed; if it be only slightly carious, it may be scraped or gouged out; and, if healthy, in accordance with that principle of conservative surgery by which no sound part is removed, it should be left, becoming consolidated with and strengthening the joint. The articular surface of the patella on the thigh-bone, which extends some way up its forepart, may advantageously be sliced off, so as to leave an osseous surface, instead of a cartilaginous one, for the attachment of the patella.

I have always found the operation, as it has just been described, easy of performance and good in its results; but various modifications are adopted by different Surgeons. Thus, some make one straight transverse incision; others two parallel incisions, one on each side of the patella, or an H-shaped incision, and thus open the articulation from the side. Jones, of Jersey, who had great experience in this operation, advised that the skin be dissected up by means of a semilunar incision, and then that the ligamentum

patella be preserved by being pushed with the patella and the quadriceps extensor tendon to one side, the joint then opened, and the bones sawn. Others advise that the patella be always removed. Volkmann recommends a straight incision, passing from one condyle of the femur to the other transversely across the middle of the patella, which is then sawn through so as to expose the joint. After the articular ends of the femur and tibia have been removed, the fragments of the patella are united to each other by sutures of catgut, carbolized silk, or wire. If its articular surface is diseased, it must be sliced off or scraped. The results obtained by this method are very good; the patella readily unites by bone, and either remains movable or becomes fixed to the femur. The attachment of the quadriceps extensor and ligamentum patellæ being undisturbed, the tendency to displacement of the tibia backwards after the operation is counteracted, and in walking the action of the rectus in bringing the limb forwards is preserved.

R. Davy, of the Westminster Hospital, has very ingeniously and successfully modified the operation of excision of the knee-joint by uniting the bones on the "Tenon and Mortice" principle, thus securing more solid bony ankylosis. He cuts the end of the femur into a wedge-shape, constituting the tenon, and cuts out a mortice in the upper end of the tibia, into which the wedge-shaped end of the femur is driven, and maintained with absolute fixity by means of a wire splint with foot-piece. This is disturbed as little as possible until firm union is established.

After the ends of the bones have been removed, in cases of white swelling, the pulpy granulation-tissue representing the synovial membrane must be cleaned away as completely as possible, partly by scraping with a sharp spoon and partly by the use of scissors and forceps. Some caution is necessary in cleaning the posterior part of the joint to avoid wounding the popliteal vessels. The healing of the wound is much facilitated and the subsequent suppuration diminished by this proceeding. If sinuses existed before the operation, they may be scraped and cleaned with a solution of chloride of zinc.

In order to keep the bones in position, some Surgeons drill them obliquely at the anterior part and secure them by a couple of strong sutures of catgut, carbolized silk, or wire. Strong catgut answers the purpose very well, and will not soften for about two weeks, after which time it is no longer needed. If the wound is not aseptic, wire sutures are the best, if any be used.

It is very important that all hemorrhage should be thoroughly arrested before the wound is closed. In some cases no ligatures will be required, but usually two or three of the articular arteries furnish sufficient hemorrhage to require restraint. The flap when laid down will often appear inconveniently long and thick, but it must not be curtailed, as it will eventually contract and fit well. As a rule, drainage-tubes are not necessary, and the flap, having no tendency to become displaced, only requires a few sutures to hold it in position.

The result of the operation will depend mainly on the care taken in the after-treatment, and in the successful prevention of decomposition in the discharges. It is essential for success that the limb should be kept at perfect rest for the first few weeks; any apparatus, therefore, which requires complete removal for dressing the wound should be avoided. A narrow splint of japanned iron, extending from the buttock to the heel, will usually answer the purpose sufficiently well. It must be padded where it is in contact with the thigh and the calf to such an extent that it is not in actual contact with the skin in the ham. It must be fixed in position by a flannel-bandage above and below the knee, over which a firm plaster-of-Paris bandage must be

applied. Heron Watson recommends a soft iron rod or bar, applied anteriorly, reaching from the groin to the toes. The upper part is straight for the thigh, in the middle is an arch passing over the knee; the lower part is straight for the leg, and bent at an angle forwards opposite the ankle to fit the dorsum of the foot. At the lower end opposite the ankle is a hook by which the limb can be suspended. The splint having been properly padded, is fixed in position with a plaster-of-Paris bandage. Thomas's splint with a foot-piece (Fig. 548) also will be found a very efficient apparatus, and may be secured above and below the knee with a plaster-of-Paris bandage. By any of these means the limb may be immovably fixed, while the knee is sufficiently exposed to allow of dressing. Whatever apparatus is chosen, it must be applied while the patient is still under chloroform before leaving the operating table. As soon as the wound is healed, the limb may be encased completely in a plaster-of-Paris or starched bandage till the bones are firmly united to each other.

If proper attention be not paid to the position of the limb, bowing outwards is apt to take place. In order to prevent displacement, it has been proposed to divide the hamstring tendons; this, however, I have never found necessary, nor does it seem to me to be advisable to complicate the operation by such an addition to it.

The best dressing for an excision of the knee is that which requires changing least frequently, and most efficiently prevents decomposition of the discharges. Whatever dressing be chosen, it should be changed at the end of the first 24 hours to get rid of the early discharge. The dry antiseptic wool-dressings, which can often be left untouched for 2 or 3 weeks, give excellent results; but if they are used, care must be taken to apply enough wool, a thickness of at least three inches being required.

The form of dressing is, however, of secondary importance to the maintenance of perfect rest. If this be attended to, osseous ankylosis will ensue, and a good and useful straight limb result. In two cases I have succeeded in getting a good limb with a partially movable joint; both these cases were in children; and I am disposed to think that in young patients this result may often be satisfactorily attained. In adults, however, osseous ankylosis should always be aimed at.

Selection of Cases for Excision.—It is generally recognized that excision of the knee should not be undertaken after the age of 30. Gant has recorded cases successfully operated on as late as 53, but these are quite exceptional. Excision is not as a rule to be recommended in very young children, as it is apt to arrest the growth of the limb to such an extent as to render it useless in after-life. Moreover, incision of the joint and scraping are usually successful at this age. About 14 or 15 is considered by most surgeons the most favorable age for the operation. It should not be undertaken when there is any visceral disease, especially if there is tubercular disease of the lungs or albuminoid degeneration of the liver. Extensive disease of the bones is unfavorable to the operation. It need hardly be said that the operation should not be undertaken when there is hope of cure by simpler means. In the International Congress of 1881 Kocher, of Berne, maintained that in white swelling excision of the knee insures a more rapid cure and a better limb than any conservative method of treatment, but this view is not generally accepted. If the disease is recognized sufficiently early, and treated properly by perfect rest of the joint, excision should be required only in exceptional cases.

Results.—In determining the propriety of performing the operation, there are two points to be considered: 1. The danger attending it, and 2. The utility of the limb left after operation.

1. Statistics have been very abundantly published with regard to the operation of excision of the knee, with the object partly of showing the absolute mortality and partly of contrasting excision with amputation. At the present time these require complete revision; first, because the death-rate has been greatly reduced by the improved after-treatment, and secondly, because many Surgeons perform the operation in hospital practice, not merely as a substitute for amputation in cases past cure by any other means, but as a means of rapid cure replacing prolonged conservative treatment.

The following are amongst the most important of the older statistical records.

Poneres, writing in 1869, gives the statistics of 600 cases in which excision of the knee had been performed. Of 431 cases operated on for disease, 300 recovered and 131 died—a mortality of 30 per cent. The result of excision for gunshot-injury has already been alluded to at p. 353, vol. i., as generally unsatisfactory.

On comparing the mortality after amputation of the thigh with that following excision of the knee-joint, some statistics show no very material difference in the rate of mortality after the two operations. In 1869, Swain found that, in 472 cases of excision of the knee-joint collected by Price, MacCormac, and himself, there were 116 deaths, or 24.5 per cent.; while in 54 amputations of the thigh there were 13 deaths, or 24 per cent. Other recent statistics, again, show decidedly in favor of excision. Willett has collected the cases that occurred at St. Bartholomew's Hospital during a period of six years. He finds that of 38 cases of excision 8 proved fatal; whilst of 84 cases of amputation of the thigh for disease no fewer than 37 died—showing a preponderance in favor of excision over amputation in the ratio of 21 against 44 per cent. of deaths. Bryant, however, says that the mortality after the two operations varies much according to age. Thus, among patients under 20 years of age, in 69 amputations of the thigh for disease of the knee, 3 only died, while of 97 cases of excision, 27 died; in 119 amputations between the ages of 20 and 40, 38 died, while of 74 excisions, 39 died. He hence concluded that, during the earlier period of life, excision is a far more fatal operation than amputation; whilst at more advanced ages, though still more fatal, the balance in favor of amputation is less striking.

The following may be given as examples of later results. Holmes states that at Guy's Hospital, where some of the Surgeons are strong advocates of early excision performed with antiseptic precautions, 89 joints were excised in a period of 5 years with only 6 deaths. Koener, also an advocate of early antiseptic excision, in 1881 recorded 64 cases with 6 deaths, 3 from septic poisoning in the early days of the antiseptic treatment, 1 from hæmorrhage, 1 from carbolic acid poisoning, and 1 from acute tuberculosis. Messing, in order to illustrate the effects of the mode of dressing, has collected 92 cases from the hospital at Kiel; 21 were performed before the introduction of the antiseptic treatment, of these, 7 died directly from the operation; 25 were treated by antiseptic methods involving frequent change of dressing, and of these 2 died; the remaining 48 cases were treated by the lasting antiseptic dressing, and of these only 1 died, from hæmophilia. Of the 72 cases, 14 underwent subsequent amputation. Sack, of Dorpat, in 1880, published the results of 144 cases treated antiseptically by various Surgeons; of these, 26 or 17.3 per cent. died: 4 from infective processes in the wound, 15 from tuberculosis and other general diseases existing before the operation, 1 from chloroform, and 1 from carbolic acid poisoning, 2 from causes unconnected with the operation, and 4 from causes not stated. Of the 119

who survived, 11 underwent subsequent amputation, making exactly 75 per cent. of successes, and 25 per cent. of failures.

2. The second point that has to be determined, is as to the *Utility of the Limb* after the operation.

On this point, the result of recorded cases is in favor of the operation. In one of Park's cases, operated on in 1794, that Surgeon states that the patient (a sailor), seven years after the operation, "was able to go aloft with considerable agility, and to perform all the duties of a seaman. In some of the latter cases the result has been equally good. One of Jones's patients (a boy) "could run and walk quickly without any aid of a stick, could stand on the limb alone, and pirouetted and hopped two or three yards without putting the sound limb to the ground." In several of my own cases an excellent, strong and straight limb has been left, useful for all ordinary purposes. In a case which I examined seven years after the operation, the limb was well nourished, straight, firmly ankylosed, and but very little shortened. The patient, a lad of twenty, could walk eight or ten miles, and even jump and stand on the limb without the least pain, sign of weakness, or difficulty. In very young children the result of the operation is not satisfactory, the leg continuing shortened and wasted, not developing with the rest of the body. This is apparently due to and dependent upon the removal of the epiphysis of the tibia, on the integrity of which the growth of that bone is dependent.

After the operation, osseous ankylosis takes place with a firm cicatrix: the limb is shortened from one to three inches, according to the amount of bone removed, but by means of a high-heeled shoe this inconvenience is greatly remedied. It has been urged against excision of the knee-joint, that convalescence is tedious and prolonged: but this argument can with justice have but little weight. If a useful limb can be preserved to the patient, it can matter but little if a few additional weeks be devoted to the procedure by which it is obtained: and indeed, it is a question whether in many cases the patient may not be able to walk just as soon after the excision of the knee-joint as after amputation of the thigh; for, as has been very properly remarked, though the amputation wound may be healed in three or four weeks, it may be as many months before an artificial limb can be worn.

On the whole, from the evidence before us, it may be concluded that in properly selected cases excision is preferable to amputation, as involving less mutilation and but little more risk. In the statistics collected by Sæck above quoted, 13 out of 20 deaths arose from visceral disease existing before the operation. If these cases had been submitted to amputation, probably many of them would have recovered, and the death-rate of the excisions would have been reduced to under 10 per cent. The operation should not be put off too long, till the patient is exhausted by pain and discharge, and the tissues round the joint perforated by numerous sinuses: but, on the other hand, it can hardly be considered justifiable to resort to excision without a fair effort to cure the disease by simple treatment. Every case must be decided on its own merits, and the results obtained will be in proportion to the judgment shown by the Surgeon in selecting the proper cases. In a doubtful case there is another consideration which cannot be altogether discarded in enabling us to form a judgment as to the preferable operation. And it is this, that, in consequence of recent improvements in surgical mechanics, artificial limbs are now constructed of so durable and useful a character, as to supply to a great extent the loss sustained by amputation, and this more particularly if the limb have been removed early in life, when the patient can more readily adapt himself to new methods of progression.

BONES OF THE LEG.—The **Tibia** is very frequently the seat of caries in the upper and lower epiphyses, and of necrosis in the shaft, requiring partial operation for the removal of the diseased portions. Occasionally a very considerable extent of the shaft, indeed the whole of it, may be removed in a state of necrosis, as a loosened sequestrum, from the interior of the periosteum, more or less consolidated and strengthened by the deposit of new bone. Such operations present nothing special, and the result is usually very satisfactory, the limb that is left being strong, useful, and sound.

The **Fibula** is less frequently the seat of operation, but it, like the tibia, may require partial removal. In one case, that of a child six years of age, I successfully removed the whole of the necrosed fibula. This operation is readily done by slitting up the sinuses in a direction so as to expose the sequestrum, which may then be drawn out without difficulty. Figs. 554 and 555. After the operation an inner splint must be applied, in order to obviate

Fig. 554. Limb with Necrosis of Fibula.

Fig. 555. Limb after Removal of Fibula.

the tendency to varus which will ensue. In the case from which the annexed drawings are taken, very considerable reparative action was set up in the periosteum and soft tissues along the line of bone that had been removed, new osseous matters apparently being deposited: and the child, when examined two years after the operation, had an excellent, well-nourished and useful limb. The foot, however, had a tendency to be drawn inwards, apparently owing to the flexors having overcome the antagonism of the peroneal extensors. This deviation inwards was counteracted by the patient wearing a properly constructed boot, with which walking was perfectly easy.

Foot.—In looking at the division of the foot into its three great component parts—toes, metatarsus, and tarsus—we shall perceive that firmness of gait is given by the foot resting on the heel behind, and on the ball in front formed by the projection of the broad line of the metatarso-phalangeal articulations, more particularly that of the great toe; whilst elasticity is communicated to the tread by the play of the toes and metatarsal bones. The elasticity of the foot may be lost without any very serious inconvenience to the patient; but the preservation of stability and firmness of gait are of essential importance; and, as these are secured by the heel, the ball of the great toe, and the breadth of the anterior part of the foot, these are the most important parts to preserve in all resections of this part of the body.

In no region of the body have the good effects of modern conservative surgery been more distinctly shown than in the Tarsus. In the "good old times" of Surgery, if a person had a "white swelling" of the bones of the foot, or a diseased tarsus, he was at once condemned to amputation of the limb. No distinction was drawn between disease of the different parts of the foot, nor any attempt made to save the sound by the sacrifice of the diseased part.

Until a comparatively recent period, indeed, "diseased tarsus" was described as a whole. Surgeons did not endeavor to make out the exact extent and amount of the disease, and any case described as "diseased tarsus" was looked upon as requiring amputation of the leg. The rule of practice then observed was, amongst the wealthier classes—those who could afford the expense of a "cork leg"—to amputate a little above the ankle; but, amongst the poorer classes, to remove the leg about a couple of inches below the knee, so as to give the patient a stump which, when bent, would fit into the socket of a wooden pin. Thus, in the latter case especially, not only was the leg—itsself perfectly sound—sacrificed, but the patient was exposed to great additional danger; for if there be one point more than another which has been indisputably proved by surgical statistics, it is, that the mortality after amputation increases, *ceteris paribus*, in exact proportion as we approach the trunk—every additional inch which we remove augmenting the danger to the patient. This practice continued to prevail until Chopart drew some distinctions between the treatment to be pursued, according as the disease affected the anterior or the posterior tarsal bones and articulations. He showed that, when the anterior articulations only were affected, amputation at the junction of the astragalus and calcaneum with the scaphoid and cuboid—an operation which goes by the name of "Chopart's amputation"—ought to be performed; thus removing the whole of the disease, and allowing the patient to recover with a shortened foot, with the heel preserved—one on which he could bear the weight of his body, and which would be highly useful to him.

The next step in the conservative surgery of the lower extremity, in cases of diseased foot, was the operation introduced by Syme—that of disarticulation at the ankle-joint. This was certainly a great advance; for, the flap being taken from the heel, the patient has a stump on which he can bear firmly. The operation is also a very safe one. According to O. Weber, 17 deaths only occurred in 101 cases of this operation. I have performed it many times without a death; and this, in the lower extremity, is extremely satisfactory.

Since the introduction of anæsthetic agents, Conservative Surgery has taken great strides; and I think Conservatism in Surgery may be regarded as the necessary result of Anæsthesia. For, although operations of this kind were performed years ago by Park, the Moreaus, and others, and their utility demonstrated, yet the operations of gouging, scraping, and partial resection were so horribly painful to the patient, and occupied so much time in their performance, that patients dreaded to submit to, and Surgeons declined to undertake, them. Of late years Surgeons have learned to discriminate disease of one part of the tarsus from that of another, and to apply appropriate treatment to each.

Looking at the subject from a diagnostic point of view—and the treatment is most intimately connected with minute and accurate diagnosis—we find that the pathology of diseases of the tarsus is closely connected with its healthy anatomy. Composed of seven bones, it presents four distinct articulations. By the term "articulation," applied to the tarsus, I do not mean

merely the connection of contiguous bones with each other, but distinct synovial sacs shut off from communication with other synovial sacs in the foot. These are well represented in the annexed diagram (Fig. 556). The *posterior calcaneo-astragaloid* is the first of them; next comes the (a) *anterior calcaneo-astragaloid*, the synovial membrane here serving also for the *astragalo-scaphoid*; the *calcaneo-cuboid* (b) is the third; and the *anterior tarsal synovial membrane* (c) is the fourth and largest of all, and the most important in a surgical aspect. It extends between the scaphoid and the three cuneiform and the cuboid bones, between the cuneiform bones themselves, between the two outer cuneiforms and the bases of the second and third metatarsal bones, and also between the external cuneiform and the cuboid. The articulation between the cuboid and last two metatarsal bones is shown at d; and e is that between the internal cuneiform and the first metatarsal bones. These two (d and e) are not, strictly speaking, tarsal joints.

In the vast majority of cases, so far as my experience goes, it is the osseous structures, and not the articulations, which are primarily diseased. The bones, being cancellous, far removed from the centre of circulation, and exposed to alternations of temperature, readily become the seat of congestion and caries, but rarely of necrosis; and in strumous subjects not unfrequently fall into a tuberculous condition. Caries, whether simple or tuberculous, once set up in bones, speedily implicates the articulations secondarily.

Now it will easily be understood, on casting an eye on the arrangement of the tarsal synovial membranes, that the extent of disease will, in a great measure, depend upon its original seat. Thus, a person may have disease in the os calcis, extending even to the cuboid, with very little likelihood of its proceeding further for a length of time. Such disease is limited to the outer part of the foot, does not involve its integrity, and readily admits of removal by operation. But let him have disease springing up in the scaphoid, or in one of the cuneiform bones, or in the bases of the second or third metatarsal bones, and the morbid process will rapidly spread through the whole of the anterior and inner part of the tarsus, and, in all probability, no operation of resection can be advantageously employed. Hence the seat of disease influences materially its amount and extent, and the kind of operation required.

When the foot is affected by strumous disease it becomes painful, the patient being unable to bear upon the toes or anterior ball of the foot. Swelling of a uniform character takes place, with tenderness at some point opposite the bones or articulations that are chiefly involved; and eventually abscesses form, leaving sinuses through which the probe passes down upon softened and carious bone. These evidences of disease are usually much marked about the dorsum and sides, where the bones are most superficial, the sole being often comparatively free—an important point in reference to operation.

The bones that are most frequently the result of primary disease are the

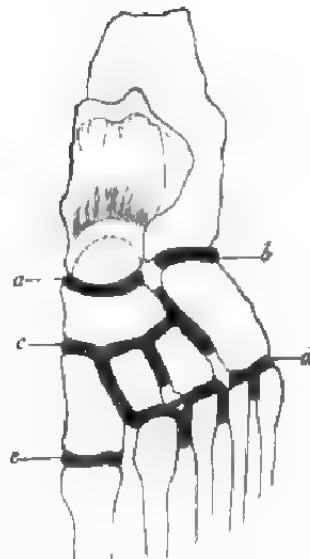

Fig. 556.—Diagram of Synovial Membranes of the Foot.

calcaneum, the astragalus, the scaphoid, the cuboid, and the metatarsal bone of the great toe. When the disease is limited to one or two of these bones, excision is usually practicable; but when it extends, through the influence of the connecting articulations, to other bones of the tarsus or metatarsus, partial amputation will probably be required.

Primary disease of the articulations of the foot is a less frequent cause of operation than caries of the tarsal bones leading secondarily to an implication of the contiguous articulations; and the particular operation required will, in a great measure, depend upon the extent of implication of the synovial membranes of the foot. When the calcaneo-astragaloid or the calcaneo-cuboid articulations are alone affected, with their contiguous bones, resection of the bones and joints implicated will often be attended by very satisfactory results; but when the large anterior tarsal synovial membrane is in a state of chronic disease, either primary or secondary to disease of the scaphoid, the cuneiform, or of either of the metatarsal bones connected with it, then resection is scarcely admissible, and Chopart's amputation offers the best means of relief. Inflammation of the large and complicated anterior tarsal synovial membrane commonly commences in disease of the scaphoid. It may, usually, be recognized readily enough in its earlier stages by the pain and swelling that take place across the line of articulation between the scaphoid and cuneiform bones, the pain being greatly increased by bending the foot down, and extending across the whole breadth of the foot. Although it is usually most severe at the inner side, which is the first affected, yet the external section of this complicated articulation, that between the external cuneiform and the cuboid, becoming involved, causes suffering to be experienced on the outer side of the foot as well. In the more advanced stages of this particular disease, the foot assumes a remarkable bulbous or clubbed appearance; the symmetry of the heel and the outline of the ankle are unimpaired, but the forepart and dorsum of the foot are greatly swollen, glazed, and sometimes perforated by sinuses discharging thin pus. I look upon this disease of the anterior tarsal synovial membrane as a distinct affection of the foot, requiring to be diagnosed from the other strumous inflammations, and in its advanced stages demanding Chopart's amputation.

It may be stated generally that the result of disease of the tarsus will be dependent mainly upon whether it is acute or chronic, progressive or stationary, diffused or limited. When it is *acute*, its limit cannot be defined, and after the removal of one portion the disease may be lighted up afresh in the structures, osseous or articular, that have been left. When *progressive*, there will be found to be a general tendency to disease in, or disorganization of, the tarsal structures, and partial operation can be productive of little good. When it is *diffused*, extending into the large anterior tarsal or tarso-metatarsal articulations, partial operation can avail nothing. It is in those cases in which the disease is *chronic*, *limited*, and *stationary*, or nearly so, that excision and partial operation can be beneficial.

Excision of Tarsal Bones.—Any one of the tarsal bones may be the seat of primary disease, which may be limited to the bone originally implicated, or may extend to neighboring articulations, or through the whole tarsus. There are, however, four bones which may be looked upon as the most frequent centres of tarsal disease—viz., the Os Calcis, the Astragalus, the Scaphoid, and Cuboid; and as regards frequency, they are commonly affected in the order given.

The *Os Calcis*, from its exposed situation, large size, and spongy structure, is more frequently the seat of caries and necrosis than any of the other tarsal bones. Very commonly the disease is limited to this bone, in other

instances it extends into the calcaneo-astragaloid or calcaneo-cuboid articulations.

When the disease is situated in the *posterior* or *lateral* part of the bone, the neighboring articulations are seldom involved, and then the removal of the morbid structures by gouging will usually succeed in effecting a cure. I have frequently had occasion in this way to scoop out great portions, sometimes the whole of the interior of the calcaneum, with the most excellent results. Even when the cuboid is extensively implicated as well, and the calcaneo-cuboid articulation is the seat of disease, the disorganized structures may often be removed by gouging and partial resection, as in the case of which the cut (Fig. 557) is a good representation, where, by means of a

Fig. 557.—Disease of Os Calcis and Cuboid and of Calcaneo-cuboid Joint; Lines of Incision.

┐-shaped incision, these bones were exposed, and their carious portions gouged out. Should, however, the caries have affected the *superior* or *anterior* portions of the bone, then the implication of the astragaloid or cuboid articulations may render the excision of the whole bone necessary, as the only means of preventing extension of secondary mischief to the tarsus generally. So unfrequent, however, is disease of the articular aspects of this bone, that its complete removal is very seldom necessary. Out of at least fifty cases of caries of the os calcis that have been under my care, I have had occasion to excise the whole bone only once; and Fergusson states that he has never yet found it necessary to do this operation. Indeed, excision of the os calcis should not be lightly undertaken. The large size of the bone, its importance as a basis of support to the body, and as the point of attachment of the strong muscles of the calf, should induce the Surgeon, whenever practicable, to avoid its complete extirpation, and to limit himself to the application of the gouge, or sharp spoon, even though he may have to scoop out the whole of the interior of the bone, leaving little more than an osseous shell. This will fill up with dense fibroid tissue, which will probably eventually undergo partial ossification, and leave the foot as useful as ever for all purposes of support and progression.

Operation.—Excision of the os calcis is usually performed by turning a heel-flap back, and then carrying incisions forward into the sole of the foot, by which another flap is turned up, and the calcaneo-cuboid articulation exposed and opened; after which the knife is carried between the astragalus and calcaneum, and the latter bone detached. By this operation the sole of the foot is somewhat extensively incised, and cicatrices are left over the heel.

In order to avoid this inconvenience, I have found that exarticulation of the os calcis may readily be performed in the following way. The patient lying on his face, a horseshoe-incision is carried from a little in front of the calcaneo-cuboid articulation round the heel, along the sides of the foot, to a corresponding point on the opposite side. This elliptic flap thus formed is dissected up, the knife being carried close to the bone, and the whole under surface of the os calcis thus exposed. A perpendicular incision, about two inches in length, is then made behind the heel, through the tendon *Achillis*, in the mid-line and into the horizontal one. The tendon is then detached from its insertion and the two lateral flaps are dissected up, the knife being kept

close to the bones, from which the soft parts are well cleared (Fig. 558). The blade is then carried over the upper and posterior part of the *os calcis*, the articulation is opened, the interosseous ligaments are divided, and then, by a few touches with the point, the bone is detached from its connections with the cuboid. This bone, together with the astragalus, must then be examined; and if any disease be met with, the gouge should be applied. Should ankylosis have taken place between the *os calcis* and the astragalus, as I have found in one case, the bones may readily be divided by means of

Fig. 558.—Excision of the *Os Calcis*.

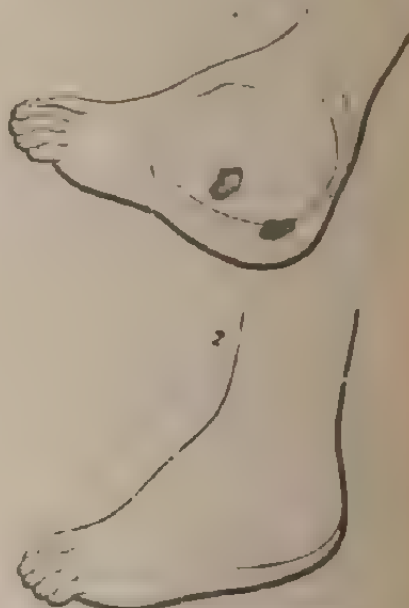

Fig. 559.—Disease of the *Os Calcis*.

1. Foot before Operation. 2. Foot after Excision.

Butcher's saw. By this operation all injury to the sole is avoided; and the open angle of the wound being the most dependent, a ready outlet is afforded for the discharges.

The drawing, Fig. 559, gives an excellent representation of the state of the foot of a girl before and after the excision of a diseased *os calcis*—a somewhat flattened but most useful foot resulting.

Subperiosteal Excision.—Olier has described a mode of removing the *os calcis*, in such a way that the periosteum may be preserved so as to allow the regeneration of the bone. A curved incision, commencing on the outside of the *tendo Achillis*, at the level of the ankle-joint, is carried down as far as the external tuberosity of the *os calcis*, and thence along the side of the foot as far as the posterior end of the fifth metatarsal bone. The flap being raised, the periosteum and *tendo Achillis* are separated from the bone, which is then further denuded of its periosteum as far as can be reached,

the ligamentous attachments are divided, and the bone is removed. In fact, in caries of the os calcis, it may often be found, as in performing Syme's amputation, that the thickened periosteum strips off the softened and carious bone as readily as the peel off an orange; hence a formal process of dissection is scarcely needed.

History and Results.—Excision of the os calcis is a very successful operation. It seems to have been first performed by Monteggia in 1813; the result appeared promising, when the patient died of scrofulous disease. The operation then fell into abeyance for twenty-four years, when Robert, in 1837, in a case of necrosis of the bone, removed the diseased portion, leaving the healthy peripheral layer. The same Surgeon, in 1844, in a case of caries, removed the whole bone with the exception of its upper articular surface and the inner side of the body. Greenhow, of Newcastle, in this country, and Rigaud, in France, appear to have been the first Surgeons who successfully excised the whole of the os calcis. Their cases both occurred in 1848; and since that time the operation has been performed in a large number of cases in this country and in America, and established as one of the many important developments made in late years by Conservative Surgery. In France, it seems to have met with little favor, though it has been successfully performed there in several instances, by Ollier, Giraudeau, and some other Surgeons. Guérin says that the operation should not be attempted: and gives as his only reason for describing the operative procedure, that English Surgeons have not feared to undertake it.

Polaillon, of Paris, in an able article written in 1869, with the object of advocating the performance of the operation, has collected the records of 64 cases. Of these he sets aside 9, of which he has not been able to find sufficiently accurate statements as to the result. Of the remaining 55, 39 were successful—this term implying that the patients were enabled afterwards to walk without artificial apparatus or support. Of the remaining 16, in 6, crutches or other apparatus were necessary; in 7, subsequent amputation was demanded on account of return of the disease or inutility of the foot; and there were 3 deaths. Resection of the entire bone—in a few cases with other portions of the tarsus—appears to have been performed in 39 of the 55 cases; of these, 30 were altogether successful; in 4, artificial support was necessary; 2 required subsequent amputation; and 3 died. The operation, according to Polaillon, has been more successful in children than in adults. He states that, of 12 cases under 10 years old, all were successful; between the ages of 10 and 20, there were 14 successful cases, and 3 failures; between 20 and 30, 7 successes and 9 failures; and between 30 and 40, 6 successful cases and 3 failures. Reproduction of the bone occurred in 12 cases; 11 being in individuals under 20 years of age.

The *Astragalus* is situated in a position of great surgical importance. Articulating with the malleolar arch above, with the calcaneum below, and with the scaphoid in front—forming, as it were, the keystone of the foot—it is perfectly evident that any disease commencing in it is very likely to spread to and involve all the more important structures of the foot. Seldom, indeed, does disease originating in this bone long remain confined to it; and, so far as my experience goes, gouging operations, even if performed at an early period, are rarely of much benefit, the morbid process continuing to extend notwithstanding their employment. Indeed, in diseased astragalus, I believe that excision ought, as a rule, to be practised in preference to gouging, contrary to what is the case in the calcaneum.

Disease primarily originating in the astragalus may spread in three directions: upwards into the ankle-joint, downwards to the calcaneum, forwards

to the scaphoid, and thence through the large anterior synovial membrane to the rest of the tarsal bones. The treatment will vary according to the direction and extent of the disease. It may be arranged under four heads.

Fig. 560.—Innecase of Astragalus.

1. When the *astragalus alius* is diseased, we find what is seen in the drawing (Fig. 560) which represents the foot of a boy whose astragalus I excised—*scilicet* just in front of the transverse arch, with fistulous openings leading down to the diseased astragalus.

lus; the anterior part of the foot and the heel being quite sound. If the disease be limited to the outer side of the bone, or to its head, it is possible that, by freely opening the sinuses and applying the gouge, the caries may be entirely removed. But this operation is not so satisfactory here as elsewhere in the foot, as it is by no means easy to avoid opening the astragalus-scaphoid articulation; and if this be done, disease will almost inevitably extend through the tarsal articulations. Excision of the astragalus alone, though sometimes required for disease, is perhaps more frequently called for in those cases of compound dislocation in which the bone, having been thrown out of its bed, eventually becomes carious or necrotic.

The operation of excision of the whole of the astragalus for disease may be done as follows. A curved incision, from four to six inches in length, should be made immediately behind the outer malleolus, and carried forward on the outer part of the dorsum of the foot to opposite the forepart of the bone. The divisions of the external lateral ligament of the ankle-joint are then cut across; the tendons of the peroneus brevis and tertius, and the extensor brevis digitorum muscle, divided. But the mass of extensor tendons in front of the foot, with the dorsalis pedis artery, must be left untouched. These should be drawn forcibly inwards. The peroneus longus tendon may be drawn backwards. The foot is then strongly twisted inwards, the astragalus cleared, and its ligaments divided from the outer side in succession as they present themselves. When the operation is done for disease of the bone, these structures will usually be more or less softened and disorganized; when for injury, they will in a great measure have been torn through. Hence, in actual operation, the same steps cannot be followed so methodically as may be done on the dead subject. The bone must now be seized with lion-forceps and drawn well out of its bed; the knife being applied to any restraining structures, but being used very carefully towards the inner side of the bone, lest the plantar arteries be wounded. Under this process the softened and carious bone usually breaks down and has to be taken away piecemeal, or its neck may be cut across, and the head separately removed from its articulation with the scaphoid. If the bone have been dislocated, and its ligamentous connections thus torn through, or if these have been disorganized and softened by disease, it may readily enough be removed as just described. But if the osseous tissue itself be carious and softened, and the ligamentous connections tolerably sound, then the operation becomes extremely troublesome, tedious, and prolonged—the bone breaking down, and having to be removed piecemeal by means of the gouge and pliers.

The *result* of this operation is very satisfactory; a good and movable articulation may be left between the malleolus and calcaneum, and the limb is but little shortened. According to Harewood, of 109 cases in which the astragalus was removed, 76 recovered with good and useful limbs; secondary

amputation was performed in two, with one death; 15 others died; and in 14 the results are not known. The operation was performed in 64 cases for compound dislocation, with 50 complete recoveries; in 20 of simple dislocation, with 14 complete recoveries; and in 10 for caries, perfect recovery taking place in 6.

2. When the disease has extended from the astragalus to the malleolar arch, *excision of the ankle-joint* will be required. This operation may most conveniently be performed in the following way. A semilunar incision, about four inches in length, should be made along the outer and inferior aspect of the joint, round the lower border of the external malleolus (Fig. 560), and should be carried sufficiently forwards to give space without dividing the extensor tendons or the dorsal artery. A perpendicular cut should then be made along the back of the fibula. The peroneal tendons need not be divided, but should be drawn downwards and backwards; the lower end of the fibula should next be cut across and detached. The astragalus, which will now be exposed, should then be separated from its connections, which, if they be much diseased, may usually be readily done. If not deeply affected, it will be more firmly held, and should then be cut across with pliers, and each fragment lifted out of its bed with gouge or pliers. The foot may next be well drawn to the inner side, and the lower end of the tibia carefully isolated; the knife being used with great caution, and kept close to the bone, lest the posterior tibial artery be injured, or the soft parts may be stripped from the bone with a periosteal elevator. When the ligamentous structures attached to the bone have been separated, the inner malleolus is cut off with bone-forceps, and as much as necessary of the lower end of the tibia removed by a gouge or chain-saw. Should there be any disease of the articular surfaces of the calcaneum or scaphoid, this must be gouged away. After the operation the limb must be placed on a suitable splint (Fig. 561).

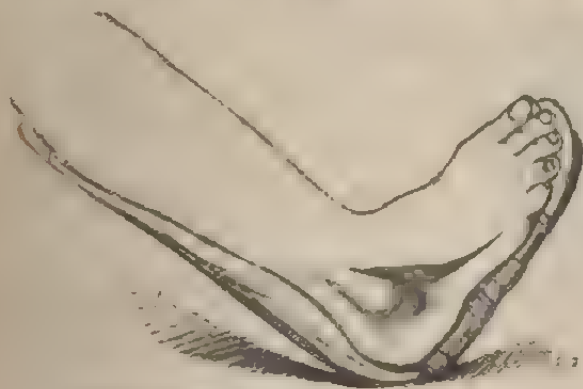

Fig. 561.—Limb after Excision of the Ankle Joint.

3. When the disease has extended from the astragalus upwards into the malleolar arch, and downwards into the calcaneum, the line of practice will depend on the extent of the implication of the os calcis. If the greater part or the whole of this be involved, no resource is left but amputation—resection not leaving a useful foot. If, however, the calcaneum be only partly involved, its upper surface only being affected, a great deal may be done by conservative surgery. The treatment in such cases consists, generally, in removing the astragalus from its bed, and gouging away any diseased bone which may exist either on the upper surface of the calcaneum or on the under surface

of the malleolar arch. Very large portions of bone may be removed from this situation. I have taken away the whole of the malleolar arch and astragalus, and gouged out the upper surface of the os calcis very freely; and yet the patient has recovered with a strong and movable foot, but very little shortened or deformed.

The accompanying cuts (Fig. 562) are taken from a young man on whom I performed the operation just described. The foot is perfectly useful and

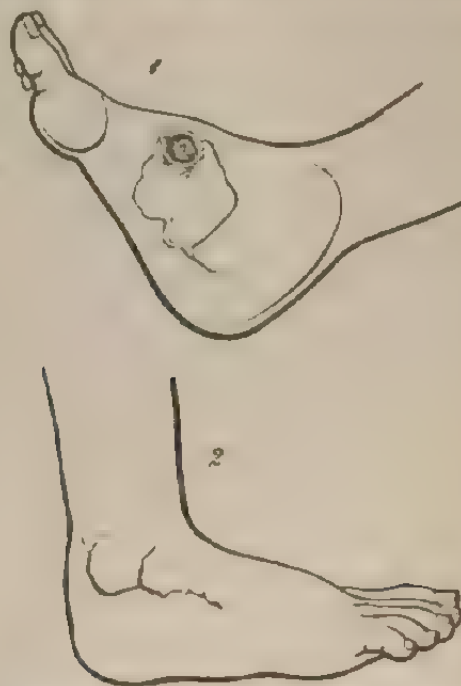

Fig. 562.—Excision of Astragalus. 1. Foot before Operation. 2. Foot six months after the removal of the Malleolar Arch, both Malleoli, the Astragalus, and a portion of the Upper Surface of the Calcaneum.

strong, and the false joint at the ankle movable. There are cases in which we find that the disease has extended so far beyond its primary seat, that amputation rather than resection is required. But, in the majority of instances, removal of the astragalus and gouging away the upper surface of the calcaneum will suffice.

The result of excision of the tibio-tarsal articulation is generally good. Spillman says that of 73 cases 50 were successful. Among these, the outer malleolus was removed in 22, 1 of which required secondary amputation, and 4 died. This leaves 51 cases of removal of the tibio-tarsal joint; in 12 of these, the disease was of traumatic origin, and the operation was successful in 11; in 37 it was constitutional, and of these 22 recovered, 7 died, 7 required secondary amputation, and in 1 the disease continued two years after the operation.

4. If the disease have extended from the astragalus to the scaphoid, and thence into the anterior range of tarsal joints, the foot will have become so

extensively disorganized, that partial resection will be of little or no service; and disarticulation at the ankle-joint should be practised.

Excision of the Cuboid Bone, either in whole or in part, may be required. Partial excision is here done with the gouge. When the whole of the bone is taken away, the fifth metatarsal bone also, with the little toe, will probably require removal. This may be done by making the flap, as depicted in Fig. 562, only commencing the incision about an inch further back, opposite the calcaneo-cuboid articulation, and opening this instead of the metatarsal

The **Scaphoid Bone** is very commonly the seat of primary disease; and, as it is connected in front with the large tarsal synovial membrane, and posteriorly with that which is common to the calcaneo-astragaloid and astragalocuboid articulations, the greater part of the tarsus is apt to become severely involved. It stands, indeed, next to the astragalus in its power of supporting a great extent of the foot when diseased. The extent of this affection is such, that excision of the primarily diseased bone would probably be attended by much benefit, and Chopart's amputation or disarticulation at the ankle-joint becomes necessary. Next to disease of the astragalus, I look upon stromous inflammation and caries of the scaphoid as most destructive to the integrity of the foot.

When the **Cuneiform Bones** are the seat of caries, it will generally be found that the middle cuneiform is the bone primarily affected. Thence the disease extends to the lateral ones, or to the bases of the second and third metatarsal bones (Fig. 563). In such cases the anterior tarsal synovial membrane usually becomes extensively implicated, and Chopart's amputation will be required. But if the disease continue to be limited to the middle cuneiform and the contiguous metatarsal bones, and the patient's general health be good, removal of the affected osseous structures by the gouge, and extraction of the carious cuneiform, may be effected by successful results.

Excision of more than one of the Tarsal Bones is sometimes required in chronic disease, and may leave an excellent and useful limb. No formal rules for the operation can be laid down; the mode of proceeding must depend on the nature of the case and the judgment of the Surgeon. In a case which was many years since under my care with very extensive and chronic disease of these parts, I removed the lower three inches of the tibia, and gouged away considerable portions of the end of the tibia and of the astragalus, calcaneum, and cuboid—removing a whole handful of carious bone; yet a perfect cure resulted, the patient recovering with a strong and useful foot.

The **os calcis** and **astragalus** have been both successfully removed by T. Walker in 1842, and by Watson, of Edinburgh; and the **os calcis**, almost the whole **astragalus**, and a part of the **scaphoid**, by Nicholls, of Chelmsford. Mr. Walker, in a case of disease of the tarsus consequent on compound dislocation, removed the greater part of the **scaphoid**, half the **os calcis**, all the **astragalus**, and the lower end of the **tibia**. Fayer removed the articular ends of the **tibia** and **fibula**, the **os calcis**, **astragalus**, and **scaphoid** for disease, in a boy 9 years old; and Lehmann, of Polzin, in a case of caries in a man aged 40, removed by subperiosteal excision the entire **os calcis**, the

Fig 563.—Disease of Cuneiform Bones

astragalus, and the scaphoid bones, the foot having a perfectly normal appearance three months after the operation, and the patient being able to walk well, without a stick.

In infants and very young children, disease of the tarsal articulations and even bones may often be recovered from, without the necessity of having recourse to operation, by attention to the child's general health, and by giving the part rest.

The **Malleoli** alone seldom require resection. Should either of them do so, the operation may readily enough be accomplished, in the outer malleolus, by dividing the bone with cutting pliers; but in the inner malleolus, more care is required in avoiding the flexor tendons, the artery, and nerve, and the bone had better be cut across with a chain saw. The peroneum should be saved as much as possible. The removal of the outer malleolus, or rather of the lower end of the fibula, is apt to be followed by a tendency to twist of the foot outwards—in fact, to a kind of valgus.

The **Metatarsal Bones with their Toes** occasionally require removal. This is more particularly the case with the first and the fifth—p. 133, vol. 1. The middle metatarsal bones cannot advantageously be taken away, leaving merely the first and last; but the two, three, or even the whole four of the external metatarsal bones may be resected in early life, and a useful foot left. Aston Key has recorded a case in which, in consequence of injury he amputated the four outer metatarsal bones, the cuboid, and the external and middle cuneiform, leaving merely the line of bones supporting the great toe. The first metatarsal bone was left, supported only by the slender articular surface of the internal cuneiform; but it soon got firmer attachments, and a very good foot resulted, by which the patient retained in a great measure his elasticity of tread.

The **Phalanges and Articulations of the Toes** seldom require resection. as a general rule, their amputation is preferable.

The **Great Toe** not unfrequently requires removal, in whole or in part; but, as it enters largely into the formation of the arch of the foot, no more of it should be taken away than is absolutely necessary. It is especially of importance that the ball of the great toe, if possible, be preserved, and occasionally this may be effected by excision of the metatarsophalangeal articulation rather than by the amputation of the member. With regard to the removal of the toe and its metatarsal bone, I must refer to p. 134, vol. 1. Whenever it is practicable, the proximal end of the bone should be saved, in order that the insertion of the tendon of the peroneus longus may be preserved.

AMPUTATION IN JOINT-DISEASES.

In those cases in which excision of the diseased joint is not advisable in consequence of the acute character of the articular disease, the existence not only of considerable suppuration but of great local and constitutional irritation, or the peculiar nature of the joint affected, amputation may be the sole resource left to the Surgeon. It is especially in articular disease of the fingers and toes, of the tarsus, carpus, ankle, and knee, that this operation is required; and though it is much less frequently practised now than formerly, yet the cases of destructive disease of joints requiring amputation are amongst the most frequent in operative surgery and will doubtless continue to be so. The Surgeon, however, must be careful, whilst he avoids continuing to make ineffectual attempts to save the limb at the great hazard of the patient's life, not to amputate until it is clear that all other means have failed; the patient continuing to lose ground so that a further perseverance

in local and constitutional treatment would probably end in his death, excision not being practicable. So far from amputation being an opprobrium to surgery in such cases as these, I look upon it as one of the greatest triumphs of our art, that by a simple and easy operation, which removes the spoiled and useless limb, the life of the patient may be saved, and his health speedily restored.

In amputating in cases of chronic joint-disease, in which the limb has been the seat of prolonged suppuration, it will be found, just as in many cases of secondary amputation after injuries, that the condition of the muscles of the limb is peculiar. Instead of, as in cases of primary amputation, being dark in color and retracting forcibly and unequally when cut across, they will be found to be pale, soft, flabby, and retracting but little, if at all; resembling in this respect the muscles in a dead body. In consequence of this alteration in their structure and physiological properties, the flaps need not be cut so long in amputation for chronic suppurative joint-disease as in cases of primary amputation.

Circumstances influencing Mortality.—The mortality after amputation for joint-diseases is especially influenced by three conditions: viz., the Seat of the Operation, the Acute or Chronic Character of the Disease, and the Constitutional Condition of the Patient.

The influence of the *seat of operation* has already been discussed at p. 107, vol. i.

The *duration of the disease* exercises a most important influence, especially in the larger joints—more particularly the knee. As a general rule, it may be stated that, the more accurate the suppurative destruction of a joint, the more successful is the amputation of the limb likely to be; pyæmia being especially apt to supervene. (See p. 107, vol. i.)

In very acute cases, the Surgeon ought to evacuate the pus by means of free incisions, and endeavor to postpone amputation until the active suppurative stage has passed, and the affection has subsided into a chronic form. In chronic cases, the success of amputation is very great. It commonly happens that a patient who has been racked with pain, and been wasting in bed for weeks before the local source of irritation was removed, sleeps soundly the night after the operation, and rapidly gains flesh and strength.

In determining upon the advisability of resecting a diseased joint or of amputating the limb, the Surgeon must be guided not only by the amount of disease in the articulation, but by the *constitutional condition* of the patient. In amputation the chief dangers are immediate—from shock or secondary hæmorrhage. In excision the shock is not so severe, in consequence of the incision being further from the trunk, and through comparatively superficial and unimportant parts; no large bloodvessels, nerves, or even muscles are divided, and there is no danger of secondary hæmorrhage. But in excision the dangers are chiefly remote; the suppurative process is often long continued, and the discharge of pus abundant; the patient may consequently not have sufficient constitutional power to carry him through. So far as erysipelas and pyæmia are concerned, the danger is probably the same in both operations. In addition to this, it must be borne in mind that a patient who would not agree to part with a limb, will often consent to have a joint or bone excised.

As phthisis not unfrequently coexists with the advanced forms of stromous joints, the question of amputation under these circumstances becomes one of very considerable importance. If the phthisis be rapidly progressing, and there be a strong hereditary tendency to the disease, or if it have advanced to softening of the lung and the formation of cavities, it will be useless to

operate. If, however, the phthisis be but slight and incipient, and the progress of the disease be apparently due to the local irritation of and discharge from the joint, to the confinement to bed that this necessitates, and to the general deprivation of health that ensues, amputation may not only be easily but advantageously practised; and I have performed it in many such cases to the manifest advantage of the patient.

CHAPTER L.

DISEASES OF THE SPINE.

SPINA BIFIDA.

It occasionally happens that, from congenital malformation consequent on arrest of development, the spinous processes of some of the vertebrae are deficient, and their laminae either absent or separated; the meninges of the spinal cord are thus unprotected, and project through the aperture in the bones, giving rise to a tumor at the part where the arrest of development in the osseous structures occurs.

CHARACTERS.—The tumor in spina bifida is usually oval its long axis corresponding with that of the spine. It varies in size, from that of a walnut to an orange; but occasionally it attains an immense bulk equal to that of a child's head. In some cases the tumor is lobulated, having an imperfect septum stretching across it; in other instances, two or more distinct tumors have been met with in the spine. The skin covering it is usually of normal color; but when the tumor is of considerable size, it may be thin and have a bluish or congested appearance, and present a certain degree of transparency. In these circumstances, ulceration from detention and thinning of the skin may eventually take place. On examining the tumor, which is hard, though elastic when the child is held upright, it will be found that it becomes soft when the child is laid horizontally. It sometimes becomes tense during expiration, and softer during inspiration. Fluctuation is usually perceptible, and by pressure the bulk may in some cases be distinctly lessened, while at the same time increased tension may be recognized at the anterior fontanelle, thus demonstrating the connection of the sac with the subarachnoid space.

The wall of the sac in spina bifida is composed of the whole of the membranes of the cord fused together. They are covered by the skin and a varying amount of fat. Sometimes the skin is apparently wanting, or is thinned and fused with the membranes so as to be no longer recognizable.

Spina bifida may be met with in any part of the vertebral column; it is, however, almost invariably found in the lumbar or lumbosacral region, this part of the spinal canal being the last to close in fetal life. The cases in which it appears higher up are of rare occurrence; instances of the kind are, however, mentioned by Cruveilhier. When it occurs in the cervical or dorsal region the spinal cord is most frequently adherent to the posterior wall of the tumor. In the lumbar region this is less common, though as the

malformation takes place at a comparatively early period of fetal life when the cord reaches to the fourth lumbar vertebra, it is not impossible for it to lie in the sac. The spinal nerves in the great majority of cases project in long loops into the sac, adhering to its walls for some distance and then returning to the intervertebral foramina.

The tumor is distended by the cerebro-spinal fluid, which is characterized by its clear, limpid appearance, by its low specific gravity (1003 to 1006 being the average), and by its containing merely a trace of albumen, a considerable quantity of chloride of sodium, and a trace of sugar. The sugar can usually be recognized only after careful separation of the albumen and concentration of the fluid by evaporation.

Spina bifida is not uncommonly associated with other deformities, especially club-foot, talipes calcaneus being the most common form. Cases also have been recorded in which the child was at the same time hydrocephalic. In these cases the central canal of the cord has been found dilated.

PROGNOSIS.—The prognosis of spina bifida will depend upon the size of the tumor, on the condition of the skin covering it, and on its situation. If it be of small size, with healthy integumental investment, and without tendency to increase, the patient may live to adult age, provided care be taken to protect the tumor. If of large size, it is generally fatal, the child usually dying at an early age of convulsions. In other instances the tumor increases, the skin covering it becomes thin and red, ulcerates, gives way, and death results from septic meningitis. It may be stated, as a general rule, that spina bifida is more dangerous the higher it is placed on the spine.

TREATMENT.—In the treatment of spina bifida, the line of practice must be determined by the size of the tumor and by the condition of the skin covering it.

When the tumor is very large, and the skin covering it has become reddened, showing a tendency to give way, tapping and compression combined offer the best chance of safety. The case from which the accompanying drawing is taken was cured in this way. It was that of a young girl. At birth the tumor was small, but it gradually increased in size, until at the age of thirteen it had attained the following dimensions: Circumference at base, 25 inches; length over greatest convexity, 19 inches; breadth, 14½ inches. The tumor occupied the lumbo-sacral, and stretched over both gluteal regions. It was tense and translucent; the skin reddened, very thin, and becoming darkly congested at the more prominent part, evidently in imminent danger of bursting. Health excellent; development good. I tapped the tumor and drew off 101 ounces of cerebro-spinal fluid. When emptied, an aperture 1½ inch long and three-quarters of an inch broad, could be felt at the lower lumbar and upper sacral regions to the left of the mesial line. The parts were well padded with cotton-wool and supported by an elastic bandage. No ill-effects followed the tapping. This was repeated nine times in eighteen weeks, 985 ounces in all of clear cerebro-spinal fluid being drawn off; the largest tapping amounted to 120 ounces; the smallest to 93. After each tapping, methodical compression was employed. The ninth tapping was followed by

Fig. 564.—Large Spina Bifida, cured by tapping and pressure.

may first be introduced and a small quantity of the fluid drawn off, but in most cases the iodo-glycerine solution may be directly injected. The puncture must be carefully closed with lint and collodion. Should the sac continue to leak at the puncture, suppuration and meningitis are very likely to occur. After the injection a flannel bandage may be applied over some cotton wool covering the tumor, and the child must be kept as far as possible in the recumbent position. A complete statistical report of this treatment has not yet been collected. At the time Morton published his paper in 1876, he knew of 14 cases in which the treatment had been tried; of these, 11 were successful. Since that time numerous successful cases have been recorded, in many of which the sac was so thin that without the operation life could not have been prolonged beyond a few weeks or months. In a considerable number of other cases neither good nor harm resulted from the treatment, and in two at least sudden or rapid death has occurred after the injection. Still, when we consider the hopelessness of the disease in most cases if left to itself, the amount of success obtained has been such as to justify the treatment in all suitable cases.

Antiseptic drainage and removal of the sac have been tried, but the results have not been such as to encourage a repetition of the treatment.

CARIES OF THE SPINE—ANGULAR CURVATURE—POTT'S DISEASE.

This disease, which consists, in its full development, of destruction of the bodies of some of the vertebrae, with disintegration of the corresponding intervertebral fibro-cartilages, most commonly occurs in young children, sometimes even during the first year of life. It is, however, met with at later periods, not uncommonly commencing at puberty, and sometimes much later still. I have seen it set in after fifty.

Pathology.—Angular curvature of the spine, or "Pott's disease," as it is commonly called after Percival Pott, the celebrated Surgeon to St. Bartholomew's Hospital, who first accurately described it in 1779, may originate in two different structures of the spinal column, viz., 1, the bodies of the vertebrae, 2, the intervertebral fibro-cartilages. The relative frequency with which the disease commences in these two structures has been the subject of considerable difference of opinion, some Surgeons maintaining that in the great majority of cases the intervertebral cartilage is the starting point of the destructive inflammation, and others that it is rarely if ever primarily affected. The cause of this uncertainty seems to be that by the time the opportunity arrives for examining the diseased structures the morbid changes are so advanced that it is impossible to say where they commenced. In the vast majority, if not in all, of the specimens obtained at an early stage of the disease, from patients dying of some accidental complication, there is no doubt that the starting point of the morbid change is the bone. While, therefore, we are not in a position to deny that the disease may originate in the intervertebral disks, this mode of origin is, to say the least, rare.

The pathological processes occurring in caries of the vertebrae differ in no material respect from those already described (p. 286) as taking place in cancellous bone elsewhere. When the disease commences in the bone, the vessels of the medullary tissue are first dilated in the affected area (inflammation or congestion), the tissue next becomes infiltrated with small round cells, before which the normal structures disappear. Thus the cancellous spaces become filled with new cells, amongst which capillary loops may penetrate (granulation-tissue). The bony trabeculae enclosing the spaces are first thinned and finally completely absorbed by the advancing cell-growth; thus a portion of the cancellous tissue of the body of a vertebra may be de-

destroyed, its place being occupied by granulation-tissue. These changes form an essential part of all varieties of caries; the fate of the granulation-tissue, however, differs in different cases, the following being the chief modifications of the subsequent processes:

1. The granulation-tissue replacing the cancellous bone may be absorbed apparently as the result of the pressure exerted upon it by the weight of the trunk. Thus a steadily progressive destruction of bone may take place without there being any extensive accumulation of granulation-tissue, and without the formation of pus. This *dry caries*, as it is termed, is very common in the spine, being the process that takes place in those numerous cases of angular curvature in which the patient escapes without the formation of an abscess. Its progress is sometimes very rapid, leading to great deformity in a very short time.

2. Instead of being absorbed, the granulation-tissue may undergo fatty degeneration, and a slow process of suppuration, with the formation of *early pus*, may take place. The pus gradually accumulates, forming a *chronic abscess*, which slowly forces its way to the surface, following the lines of least resistance.

3. The granulation-tissue may *calcify* early, before the bony trabeculae are completely absorbed. The unabsorbed bone then perishes, forming *sequestra*. This *necrotic caries* is very common in the spine.

4. The granulation-tissue may *calcify*. This is not uncommon in the spine. It is said to be one mode of cure, especially when the disease is tubercular and the area affected very limited, the small calcified nodule lying harmlessly embedded in the surrounding bone. Small necrosed fragments of cancellous bone with its spaces filled with calcified inflammatory products, are sometimes met with in the discharge from abscesses connected with angular curvature of the spine.

5. Lastly, if all sources of irritation are removed, the rarefying *ostitis* may cease to extend, and the granulation-tissue become developed into bone, thus effecting a cure of the disease. The points at which caries most commonly commences, are first, in the growing tissue between the cartilaginous disks forming the upper and lower parts of the body of the vertebra; secondly, beneath the periosteum in front; and, thirdly, in the central parts of the bone.

The destructive process extends not only into the bone, but also, usually at an early period, into the intervertebral fibro-cartilages. As the disease commences most commonly between the epiphyseal cartilage and the bone, the thin layer of cartilage is soon destroyed by the same processes as are observed in the destruction of articular cartilage in chronic inflammation of joints (p. 350). The granulation-tissue then penetrates into the intervertebral disk, which is destroyed, after which the morbid process extends into the body of the next vertebra.

The *causes* of the disease when it commences in the bone are, first, injury in an unhealthy subject, and, secondly, deposit of tubercle. The fact that the most common starting point is the soft growing tissue between the bone and the epiphyseal layer of cartilage, and that it is usually situated at the anterior part which would be most powerfully compressed during forcible flexion of the spine, is strong evidence that the primary cause of the disease is frequently an *injury*. In some cases there is a clear history of injury, such as a fall, but as the disease is most common in young children and commences insidiously, the history cannot, as a rule, be implicitly relied upon. That the disease is in a very large proportion of cases due to the *deposit of tubercle* is now almost universally recognized. The evidence in proof of this is the following. First, the disease frequently commences in many independent

centres, often in the bodies of different vertebrae, and in situations, such as the front of a body or in its central parts, which are little exposed to injury. Secondly, in patients dying of advanced caries affecting one part of the spine separate centres of disease in an earlier stage are frequently found in other vertebrae. The granulation-tissue removed from these has been shown to contain non-vascular, caseating nodules presenting the characteristic anatomical structure of the tubercle-nodule or follicle (vol. i. p. 1010), and further the presence of the tubercle-bacillus has been demonstrated in many cases. Thirdly, the early caseation of the inflammatory products and the chronic suppuration correspond with the course followed in tubercular inflammations elsewhere. And, lastly, a considerable proportion of patients dying of caries of the spine are found to be infected with general tuberculosis.

In whatever way the disease commences, the most common cause of its persistence is the mechanical irritation of the diseased surfaces by the friction of movement, aggravated by the weight of the parts of the body above the affected vertebrae. In other cases the presence of sequestra, which cannot find a way out, may keep up the disease indefinitely. It seems probable that caries originally tubercular may become simple in character as the disease progresses. The original tubercular centre may completely caseate and soften, exciting inflammation in the tissue around it, and be thus eliminated, the subsequent progress of the disease being due to the mechanical causes above mentioned. In other cases the tubercular process may infect the surrounding parts and maintain its characteristics to the end.

I know of no exact description of any *primary pathological changes taking place in the intervertebral disks*. As before stated, we are not in a position to deny that disease may originate in these structures, but by the time the case comes to be examined after death the fibro-cartilage has disappeared, and we find only the signs of rarefying osteitis in the vertebrae on each side. Lushka states that there is a synovial cavity in each disk, and that the lobes of the pulp correspond to the villi of a synovial membrane. If this be true, it would be in this structure that any primary inflammation or deposit of tubercle would take place, and not in the dense fibrous and fibro-cartilaginous layers forming the outer zones of the disk.

The nature of the pathological changes being borne in mind, the coarser morbid appearances are easily understood.

Dry caries, or caries without suppuration, forms the simplest variety of the disease. It affects usually a limited portion of the spine, often two vertebrae only with the intervening intervertebral disk. The destruction of the bodies of the vertebrae in these cases often takes place somewhat rapidly, and at the same time the osseous tissue is softened by extension of the rarefying osteitis for some distance from the centre of the disease. In consequence of this, the weight of the body above the diseased vertebrae causes a bending forwards of that portion of the column, and a corresponding projection backwards of the spinous processes. A vertical section made through a spine thus affected shows the anterior common ligament thickened and swollen. The bodies of the affected vertebrae are softened and partly destroyed, the destruction being almost invariably more extensive anteriorly, as this part is exposed to the greater pressure when the spine is bent forwards. The intervertebral cartilage between the two vertebrae has more or less completely disappeared; if any remains, it will be at the posterior part. The opposed surfaces of the vertebrae are covered by granulation-tissue, and are sometimes mutually adapted to each other as the result of friction. In the cancellous spaces of the bone on each side the normal medulla has disappeared, and its place is taken by the same tissue. The periosteum covering the remaining portion of the vertebrae and frequently also that of the vertebrae above and below is

affected by osteoplastic inflammation, irregular spiculated nodules of new bone being formed beneath it. The spines, the transverse and the articular processes being unaffected, there is no dislocation, and consequently the spinal canal is but little if at all narrowed. Should the disease cease at this stage, as it frequently does, the granulation-tissue of the opposed surfaces coalesces, and subsequently becomes developed into bone, and the angle formed by the bending of the spine is filled up by a buttress of bone formed beneath the periosteum, and thus the spine, although retaining its deformed position, may become as strong as before the disease (Fig. 565).

Fig. 565.—Angular Curvature of the Dorsal Spine from Caries and Ankylosis.

Fig. 566.—Caries of Bodies of Lumbar Vertebrae, no attempt at Ankylosis.

In other cases of caries of the spine the disease is more extensive, commencing from many centres, often situated in different vertebrae and unconnected with each other. These centres are situated most commonly in the immediate neighborhood of an intervertebral disk, but are not uncommon on the surface of the body beneath the periosteum, and are sometimes deeply in its substance. A macerated specimen shows the bone to be eaten out into irregular hollows, around which the cancellous tissue is more porous than natural. In a fresh specimen these hollows are filled with caseous granulation-tissue. When the disease commences near an intervertebral disk, this is soon destroyed, and the contiguous surface of the next vertebra becomes implicated (Fig. 566). The friction of the diseased surfaces against each other then aggravates the process, and leads to more rapid destruction at the parts where they are in contact. It is this form beginning in numerous centres that is most evidently tubercular, and most frequently terminates in suppuration.

In some cases instead of the bone being more spongy than natural round the excavations, it may be seen in the macerated specimen that the osteitis has assumed an osteoplastic form, the cancellous tissue being denser than natural, and its trabeculae thickened, just as a zone of dense bone is often found around a chronic abscess in the cancellous ends of the long bones.

When the disease leads to suppuration, the pus frequently raises the anterior common ligament from the vertebrae for some distance. This is more

likely to happen when the resulting chronic abscess has opened externally and become septic from the admission of impure air. Rapid destruction of the intervertebral disks with which the pus comes in contact then frequently takes place. It is not uncommon to find the vertebrae for some distance above and below the centre of disease bare in front, and looking as if macerated, while the cartilages between them have more or less completely disappeared.

The chronic abscesses forming in connection with caries of the spine are directed to the lateral aspect of the bodies of the vertebrae by the great thickness of the anterior common ligament. As the pus accumulates the abscess makes its way, as in the case of chronic abscesses generally, in the direction of least resistance, usually following the course of a vessel or burrowing beneath the fascia covering muscles. Thus in disease of the dorsal vertebrae, the abscess follows the intercostal artery and passes between the ribs with the posterior branch, appearing under the skin of the back as a "dorsal abscess." In the lumbar region the abscess may in the same way follow a lumbar artery and form a "lumbar abscess," or enter the sheath of the psoas muscle and form a "psoas abscess," pointing below Poupart's ligament.

When the caries is complicated by necrosis, the sequestra are frequently so entangled in the excavated cavity in the body of the vertebrae, covered in in front by the thickened anterior ligament, that it is impossible for them to make their way to the surface, and thus even if the disease ceases to extend, suppuration may be indefinitely prolonged till it causes the death of the patient.

The angular projection backwards of the diseased part of the spine, corresponding in extent to the amount of destruction of the vertebrae, forms

Fig. 567. Natural Curve of Spine.

Fig. 568. First Early Change of Curve in Angular Curvature.

Fig. 569. Change of Curve of Spine in Advanced Stage of Angular Curvature.

usually the most marked feature of the disease (Figs. 567-569). The mechanism of this is easily understood by reference to the pathology of the affection. The bodies (one or more) of the vertebrae, being softened or partly destroyed, at last give way under the weight of the upper part of the body; the upper part bends forwards, and the spines project posteriorly. At the same time that the upper part bends forwards, the lower part of the spine rarely maintains the upright position as it did in Fig. 567. In the

great majority of cases there is a compensating incurvation just below the excurved vertebra, and in this way the upper part of the body is carried erect. The angle of excurvation varies according to the number of vertebral bodies destroyed, and the extent of the loss of substance. The greater the number of vertebra affected, the more obtuse will the angle be. When one vertebra only or chiefly is diseased, three spinous processes will project to form the angle, that of the diseased vertebra being the apex. If two or three be diseased, five spinous processes usually enter the formation of the angle of excurvation, and then the whole of this portion of the column will be displaced backwards, giving a thickened and broadened base to the excurvation in the lateral direction. In the dorsal region, if a single vertebra is diseased, the projection is usually very marked and sharp as the bending forward of the vertebra turns the long oblique spine almost directly backwards, forming a sharp prominence. In the lumbar region, where the spines are short and point directly backwards, the projection is more rounded.

It is comparatively seldom that the spinal cord becomes compressed, injured, or diseased during the progress of this affection. It may, however, become pressed on by the sudden and acute development of the curvature, more especially in cases in which the rarefying osteitis is widely diffused through the bodies of the affected vertebra, leading to rapid and extensive softening. More or less complete paraplegia may then ensue. In other cases the cord may be compressed by thickening of the meninges, or from inflammatory exudation into the canal. In some cases in which owing to the disease attacking the posterior parts of the bodies or affecting them irregularly in such a way that the posterior excurvation of the spine is slight, the dura mater may be implicated and diffuse spinal meningitis result. This is especially likely to happen in cases complicated with abscess, if after opening the discharges are allowed to decompose. In other cases the cord may become softened opposite the seat of curvature.

The most common seat of caries of the spine is the lower dorsal or the junction of the dorsal and lumbar regions. It is not uncommon in the middle dorsal, and may occur at any part. R. W. Parker states that in 149 cases, the disease was in the cervical region in 9, in the dorsal in 82, in the dorso-lumbar in 21, and in the lumbar or lumbosacral in 37.

SYMPTOMS.—Angular curvature, or Pott's disease of the spine, commonly begins, especially in children, in a very insidious manner. It occurs usually in strumous children, and is generally referred to a fall or blow on the back. The symptom that most often first attracts attention is the child's attitude, which is altered and very characteristic. The body is held stiffly straight and upright; it is neither bent nor turned to one side when the child moves, but the spine is moved as a whole and in a rigidly fixed manner. The shoulders are raised, the chin is thrown up, and the toes are slightly turned in. The child walks with great caution, and very stiffly.

One of the earliest symptoms complained of is often an ill-defined superficial pain, extending round the trunk, more severe, perhaps, on one side than on the other, and occasionally referred to the stomach. After a time the child becomes unable to stand upright unsupported, has a tendency to lean the body forwards, or to support it by resting the hands on the knees, or by seizing hold of anything that will serve as a temporary support, such as a chair or table. It will be found also that the child experiences great difficulty in raising itself without assistance from the horizontal into the sitting position, or in turning sideways in bed without the use of its arms. On examination, one or two of the spines, usually about the middle of the back, will be found to be a little more prominent than the rest; and, on pressing or tapping upon them, pain will be complained of. The child

become stunted in its growth; and, if the disease be not arrested by proper treatment, will continue more or less hump- or round-backed for life. In other cases the disease will run on to the formation of abscess, as will immediately be described, strumous manifestations occurring elsewhere, and death eventually resulting.

In *adults* the danger and the symptoms vary according to the seat of the affection. It is most dangerous, often indeed rapidly fatal, when the cervical vertebrae are implicated; for, as the bodies of these are shallow, caries readily penetrates to the spinal canal, and the cord or its membranes may thus be implicated. When the dorsal or lumbar vertebrae become diseased, the affection is not so immediately serious to the life, as it may be to the figure of the patient. In adults it often commences with obscure aching pain in the loins or back, apparently of a rheumatic character, shooting round the body or down the thighs. On examining the spine, which feels weak to the patient, and which, as in the child, is incapable of supporting him or of enabling him to raise or turn himself without assistance, tenderness on pressure or on tapping will be experienced at one point, and he will wince when a sponge wrung out of hot water is applied to this part of the spine; although there may be no appearance of excurvation, the skin covering it is hyperæsthetic. After a time, however, the spinous process of one or more vertebrae will be found to project distinctly beyond the general line of the column. This part becomes the seat of constant aching pain, increased by movement or by pressing upon the head or shoulders. It must, however, be remembered that caries of the bodies of the vertebrae may take place to a considerable extent with little or no angular curvature. In these cases all the ordinary symptoms of caries of the spine will be found, except the excurvation. It will be observed that the spine has lost its natural free mobility and flexibility, moving fixedly, stiffly, and as a whole, when the patient leans forwards or sideways. The patient, when laid flat on his back, cannot raise himself into a sitting position without the aid of his hands or elbows, and he cannot turn sharply and suddenly over upon his face, but struggles with outstretched arms in vain attempts to do so. Occasionally the incipient curvature, when it occurs, assumes more of a lateral than of an angular direction; and in one fatal case I have seen the spine actually bent backwards, so as to be incurvated at the seat of the disease. In some cases, the true angular excurvation dependent on caries of the bodies of the vertebrae may be associated with the ordinary lateral curve of density. The lower limbs become weak, and the patient walks with a peculiar shuffling tottering gait, the legs being out-preed, and the feet turned out. The weakness of the limbs is especially marked in going upstairs, and may be tested by directing the patient to stand unsupported on one leg, and raise the other so as to place the foot upon the seat of a chair, which he will probably be unable to do. Not unfrequently there is more or less of a neurægic affection associated with the muscular weakness—a species of neurægic motor paralysis which is very characteristic. Sensation is not only perfect but over-acute in parts, whilst there is an ataxic state of the muscles of the lower extremities, presenting a peculiar and characteristic train of nervous phenomena. The deformity of the spine may slowly increase; the patient may become unable to stand; and paralysis of the

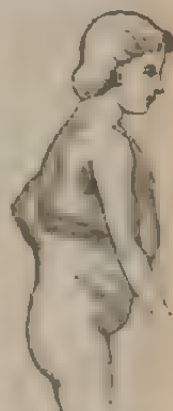

Fig. 574.—Attitude of Child in Angular Curvature in Advanced Stage.

muscles of the lower extremity may come on together with a tendency to relaxation of the sphincter ani, and retention of urine.

Paraplegia does not occur so frequently as might have been expected when we consider the very acute angle that is formed by the diseased spine in extreme cases of excurvation. But the spinal canal is not encroached upon, as there is no displacement of the laminae and transverse processes of the vertebrae in the form of dislocation, the deformity being due simply to bending forwards owing to the destruction of the bodies—hence the cord is not compressed as in a dislocation. When paraplegia does occur, it is the result of compression of the cord at the seat of disease from inflammatory exudation upon the meninges or in the canal. These become absorbed after a time, and hence the paraplegia is not of a permanent character, but will pass off after some months, or a year or two at most, even though electric irritability and sensibility may for a time have been completely lost.

Pleuritic Attacks of a localized character dependent on extension of the inflammation of the vertebral substances to the contiguous pleurae not uncommonly occur when the caries affects the dorsal spine.

Abscess commonly makes its appearance as the disease progresses; and in some cases it occurs before any of the other signs except pain and weakness of the spine, and certainly before any deformity. When the abscess forms, as Stanley has observed, the pain consequent on irritation of the spinal cord and nerves is usually lessened for a time.

It must not be supposed that abscess necessarily follows in all cases. In children, especially, we often meet with great excurvation without any suppuration. In adults it is very rare to see angular curvature without the formation of an abscess. The exact causes that determine the formation of pus are not certain in all cases. In many it is undoubtedly due to the irritation caused by the friction of the diseased surfaces against each other, and proper treatment adopted early will do much to prevent it. Suppuration is also more likely to occur when the patient is poorly fed and exposed to general unhygienic surroundings.

As cases in which abscess does not form usually recover, we have but little definite knowledge as to the exact nature of the disease, whether it is tubercular or not. On the other hand, the majority of cases in which death takes place are found to be associated with the presence of tubercle in the diseased bones. It has been assumed, therefore, that the cases of angular curvature without suppuration are due to simple inflammation, probably of traumatic origin, while those with suppuration are tubercular, but the evidence is not sufficient to justify an absolute statement to this effect.

In cases which recover without suppuration, the diseased bodies become fixed together into a single mass, across which bridges of osseous tissue are sometimes thrown out, so as to strengthen the otherwise weakened spine. Indeed, this ankylosis and fusion of the bodies of the diseased vertebrae may be looked upon as the natural mode of cure of angular curvature of the spine; the only way in which it can take place when once the disease has advanced to any considerable extent.

When pus forms in connection with diseased spine, the situation and course of the abscess depend mainly upon the part of the spine affected; thus, for instance, when the cervical vertebrae are diseased, the abscess will come forwards behind the pharynx, and may occasionally extend under the sternomastoid muscle to the side of the neck, where it opens; sometimes, though very rarely, it passes into the chest, and in other cases into the axilla.

When the disease is seated in the upper or middle dorsal spine, the abscess most commonly passes backwards between the posterior ends of the ribs,

forming a *dorsal abscess*. In some cases, however, in which the middle dorsal vertebrae are diseased, the abscess may extend downwards. When it takes this direction it most commonly passes under the ligamentum arcuatum internum, and thus enters the sheath of the psoas muscle and takes the course to be described immediately. In rare cases it may pass between the pillars of the diaphragm with the aorta and follow the large vessels in the subperitoneal tissue superficial to the fascia of the psoas and iliacus, forming an accumulation filling the iliac fossa and pointing above Poupart's ligament, or it may extend downwards into the pelvis and escape with the gluteal artery through the great sciatic notch, giving rise to a large abscess in the gluteal region. It is remarkable that in caries of the dorsal vertebrae the pus does not tend to encroach on the chest or the pleural cavity. When the lower dorsal or upper lumbar vertebrae are diseased, the pus enters the sheath of the psoas or the substance of the muscle, thus constituting the common affection termed *Psoas abscess*. A psoas abscess follows the course of the muscle from which it derives its name. It is firmly bound down in front by the fascia covering that muscle and the iliacus, which is usually considerably thickened and is never perforated by the pus. The psoas muscle is usually extensively destroyed. The pus is prevented from extending downwards into the pelvis by the attachment of the ilio-psoas fascia to the brim; there is nothing to limit its extension outwards over the whole surface of the iliacus, though the attachment of the fascia to the crest of the ilium prevents its passing beyond that point. Thus we find that a psoas abscess usually extends outwards, forming a large fluctuating swelling filling the iliac fossa. As the accumulation increases, it passes beneath Poupart's ligament, most commonly by a somewhat narrow neck situated in the line of the anterior crural nerve. It is thus at this part situated to the outer side of the femoral vessels. Fluctuation can readily be felt between the swelling on the thigh and that in the iliac fossa. There is very distinct impulse communicated to the part outside the abdomen on coughing, and this, combined with the somewhat sudden appearance of the swelling on the thigh, may make it in some respects resemble a hernia. After reaching the thigh, the abscess extends downwards to the outer side of the vessels for a short distance till it meets the profunda, and following that vessel it passes under the femoral artery, which can be felt stretching across it in front. It then continues its course under the adductor longus, and forms a large cavity at the inner side of the thigh, having the gracilis stretched over it internally, the adductor magnus behind it, and the adductor longus in front. Processes frequently extend from the main cavity along the branches of the profunda. The most common of these prolongations is one winding round the neck of the femur with the branches of the interval circumflex, and passing through the interval between the adductor magnus and the quadratus femoris, becoming superficial immediately behind the trochanter major, between it and the tuberosity of the ischium. The abscess seldom extends beyond the upper part of the thigh, but it may continue its course downwards, until it reaches the popliteal space, and may even pass some distance downwards between the deep and superficial muscles of the calf following the main vessels. I have seen an abscess, which took its origin in disease of the dorsal vertebrae, opened by the side of the tendo Achillis (Fig. 92, vol. i.). A psoas abscess, when fully developed, usually consists of four parts—a narrow track in the upper part of the psoas muscle, a wide expansion in the iliac fossa, a second narrow part extending under Poupart's ligament and the femoral vessels, and a large cavity on the inner side of the thigh. The difficulty of properly draining such a cavity by an opening in the thigh only is evident. In some

cases the abscess may follow both psoas muscles, and project in each groin at the same time.

As in the dorsal region, the abscess may pass backwards instead of downwards, and point in the loin, forming a *lumbar abscess*. More rarely it may burrow amongst the layers of the abdominal muscles and point in front. In disease of the lower lumbar vertebrae and upper part of the sacrum the pus may get beneath the fascia covering the pyriformis, and then following the nerves, may point in the buttock beneath the gluteus maximus, or it may extend downwards to the ischio-rectal fossa. In all spinal abscesses small sequestra derived from the diseased vertebrae are not uncommonly found in the pus. In the patient from whom Fig. 370 was taken, several fragments of bone thus came away from an abscess that was opened in the forepart of the thigh. Much curdy matter is usually present, making it impossible in many cases to empty the sac by aspiration. The true source of origin of these abscesses may usually be determined by an examination of the spine, and by feeling an impulse on coughing communicated to their extreme points of presentation. In psoas abscess there is some flexion of the thigh, with pain on forced extension. General oedema of the limb may occasionally arise from a psoas abscess after it has reached the inner side of the thigh. In rare cases after opening, if septic inflammation follows, the abscess cavity may ulcerate into the hip-joint, causing acute and rapidly destructive arthritis.

DIAGNOSIS.—The diagnosis of caries of the spine is made at the first sight of a patient affected by the disease, when once the angular deformity has taken place. It is, however, difficult before excurvation occurs, being indicated at this period only by the existence of pain in the back, and by some symptoms of spinal irritation. At this stage it may be mistaken for spinal or intercostal neuralgia, for rheumatism, or for stone in the kidney. The existence, however, of a continuous fixed pain in the back should always lead to a suspicion as to the true nature of the disease, lest the grievous error be committed of treating as mere neuralgia or rheumatism what may turn out to be incurable disease of the spine itself. Here the tenderness on pressure, the increased sensibility to the application of heat will determine the seat of the affection. The pain elicited by rotation or by antero-posterior movement is a very valuable symptom. In most cases pain on bending backwards is most complained of. The patient can stoop forwards, but if bent backwards suffers much. So also pressure on the head or shoulders greatly increases the pain of the part affected. The shape of the back, with loss of the natural and graceful curves of the spine with a tendency, though it be very slight, to projection of some of the spinous processes, the feeling of weakness in the back, the difficulty in rising from a sitting or horizontal position, in turning, or in standing on one leg unaided, the loss of the natural flexibility of the spine, and especially the occurrence of these symptoms in early childhood or youth, at a period when the other diseases with which it may be confounded rarely occur, and are still more rarely persistent, would lead one to suspect the existence of caries of the spine.

The diagnosis between abscesses localized in the situations mentioned and those arising from discoidal spine, is not always easy; as purulent collections of various kinds may form in the different planes of areolar tissue in the neighborhood of the vertebral column, without any disease existing in it. Thus, a large psoas abscess descending in the sheath of the muscle and presenting under Poupart's ligament, may occur from some irritation of the areolar or fascial structures without disease of any of the vertebrae. In these cases of simple abscess, the diagnosis from the psoas abscess dependent upon vertebral disease is usually easy, as there will be an absence of all excurvation of the spine, or even of tenderness along it. As psoas abscess dependent

upon vertebral caries almost invariably presents in the groin, and a large abscess in the groin may arise from various other conditions, independently of such vertebral disease, the Surgeon must attend carefully to the diagnosis of these various conditions. *Abscess and fluctuating swellings in the groin* may arise from the following causes: 1, from large chronic collections of pus in the subcutaneous or intermuscular planes of areolar tissue; 2, from disease of the areolar tissue around the kidneys; 3, from pericœcal abscess (on the right side only); 4, from iliac abscess, whether forming merely under the iliac fascia, or dependent on disease of the pelvic bones; 5, from hip-joint disease, the abscess being pelvic; 6, from large buboes or glandular abscesses; 7, from an empyema perforating the pleura and finding its way down behind the diaphragm; 8, from serous or hydatid cysts; and, 9, femoral hernia with fluid in the sac. These various collections may, however, with a little caution be readily distinguished from the ordinary form of spinal abscess that descends along the psoas muscle. In the first place, in all these cases there is an absence of that dorsal pain and tenderness, with more or less excoriation, which, though not invariably present, are commonly met with in psoas abscess. Then, again, if the collection be *perinephritic*, there will have been previous, or there are coexisting symptoms of renal disease. I have, however, seen an abscess dependent on caries of the vertebrae not only assume the perinephritic form, but open into the pelvis of the kidney, thus simulating chronic pyelitis. In this case the diagnosis was made by a careful examination of the pus, in which molecular masses of carious bone were found. The chemical and microscopic examination of the pus in all cases of doubt should never be omitted. If there be caries, it will present unmistakable evidence of the presence of disintegrated bone. If it occur in the *areolar tissue around the ureters*, the pus will be peculiarly offensive, will present itself in a less distinct manner, and will probably be associated with symptoms of intestinal irritation. Moreover, perinephritic or pericœcal abscesses being superficial to the iliac fascia, do not extend below Poupart's ligament except in some rare cases, in which the abscess is acute, and forces its way irrespective of the attachments of the fasciæ. Thus I have seen the pus in a pericœcal abscess pass under Poupart's ligament, and present as a large sloughy abscess at the upper and outer part of the thigh. In those rare cases in which an *empyema* has found its way between the layers of the abdominal muscles, and presented in the groin, the examination of the chest will point out the nature of the affection. In *abscess connected with the disease of the hip-joint*, there will be special local evidences of the source of the pus. The only real difficulty consists in diagnosing a psoas abscess dependent on disease of the vertebral column, before it reaches the thigh, from *iliac abscess*, whether it take its origin in the loose areolar tissue of the iliac fossa, or be connected with disease of the corresponding bone; and in the latter cases the difficulty is often not a little increased in consequence of the iliac abscess finding its way into the sheath of the psoas muscle. If the iliac abscess be superficial to the fascia iliaca, it very rarely passes beneath Poupart's ligament, owing to the firm attachment of these two structures to each other. In very rare cases such abscesses find their way along the spermatic cord or down the femoral sheath, and thus leave the abdomen, but these could not be confounded with psoas abscesses. When the collection of pus forms beneath the fascia iliaca, there is nothing to prevent its extending to the psoas, or passing down under Poupart's ligament, and the determination of its origin, whether from disease of the ilium, or vertebrae, or from a strain, can be made only by the presence or absence of the symptoms of disease of the spine. Whenever the abscess is beneath the fascia, there are some signs of irritation of the ilio-psoas muscle, which are usually wanting when the pus is in the subperitoneal tissue. These signs

are most marked when the abscess extends along the whole length of the psoas. There is then an inability to stand upright, to extend the leg and pain is complained of in walking. Psoas abscess also, in many cases, appears on the thigh suddenly, the patient finding, on washing himself in the morning, that he has a large soft tumor in the groin; whereas iliac abscess comes on more gradually, and presents in a more diffused and less circumscribed manner.

Iliac and psoas abscesses require to be diagnosed also from certain forms of aneurism of the abdominal aorta or iliac arteries, which, having become infused by rupture of their sac, have formed large non-pulsating extravasations in the sheath of the psoas in the iliac fossa. In such cases the previous history, the absence of distinct fluctuation, and possibly stethoscopic examination, together with the rapid increase of the tumor, will throw light on the true nature of the case.

In other cases, again, when the abscess, after deeply burrowing, has perforated the fascia lata, its feel closely resembles that of certain fatty tumors. Here the possibility of diminishing the size of the swelling on pressure and impulse on coughing, and the absence of a solid edge to the swelling enable the Surgeon to effect the diagnosis.

From femoral hernia the soft and fluctuating character of the swelling, its gradual return when pressure is taken off, its situation external to or below the femoral vessels, and all absence of gurgling, constitute the chief distinguishing characters.

Large serous collections and hydatid tumors are occasionally met with in the iliac fossa and groin, presenting in their progress, their size, and their fluctuation, all the characters of chronic abscess; from which, however, the character of the fluid let out on puncturing them will immediately distinguish them.

PROGNOSIS.—The prognosis is necessarily unfavorable. It has two aspects.

1. As to the persistence of Deformity; 2. As to the Life of the Patient.

1. **Deformity.**—The angular curvature arising from caries of the bodies of the vertebrae is necessarily an incurable deformity. The diseased spine is soldered and held together by fusion of the partly destroyed vertebral bodies, and any attempt at straightening or unfolding this excorvation would be attended by the greatest risk, from danger of exciting irritation of the spinal meninges, or opening the spinal canal. When excorvation has taken place, there has been loss of substance; and this cannot be repaired. Hence the spine must remain shortened in front and bent out posteriorly, giving rise to the ordinary form of humpback.

2. **Life.**—So far as life is concerned, the prognosis will depend on several conditions. The first is whether the disease is accompanied or not by suppuration. When suppuration occurs, much will depend on the extent of the caries: if several vertebrae be affected, so that the curve is very long, the disease is necessarily highly dangerous from the extent of osseous structure implicated. It was long ago remarked by Beyer, that the most fatal cases were generally those in which the spine preserved its straight position, whereas, when it was much curved, death seldom resulted. The truth of the remark I have had frequent occasion to verify; and the circumstance would appear to be owing to the fact that, when the spine continues straight at the same time that the bodies of the vertebrae are tuberculous and carious, ankylosis cannot occur, so that the spinal canal is open and the cord irritated, whereas, when they have fallen together and very considerable gibbosity has resulted, ankylosis more readily takes place, and thus an imperfect cure is effected. The size of the abscesses, and the amount of discharge from them, must also necessarily seriously influence the result. If they be very large, and continuously discharging, hectic and consequent death will probably

supervene. The presence of sequestra which will not come away, and prevent healing, adds greatly to the gravity of the case.

TREATMENT.—The first and great principle in the treatment of angular curvature of the spine is to take off the weight of the upper part of the body from the diseased vertebra, and at the same time to fix the vertebral column so as to prevent disturbance of the healing process, that of ankylosis, by which the mischief is repaired, and consolidation ultimately effected.

These great principles of lightening the weight upon, and securing the rest of the diseased portion of the spine, may be carried out by one of three methods, viz., 1, the maintenance of the horizontal position; 2, use of mechanical apparatus; 3, the employment of a plaster-jacket or one made of other material, moulded to the body. These various methods may be combined. Thus after the application of the plaster-of-Paris or felt-jacket, the horizontal position may be enjoined. They cannot be employed indiscriminately. One method will be more suitable than another at different ages, in different stages of the disease, or according as it affects different portions of the column.

In infants, the utmost that can be done is to enjoin strictly the maintenance of the recumbent position on a soft pillow or small couch. In children and young adults, the plaster-of-Paris jacket will be found to be most serviceable, combined with long-continued rest in the horizontal position; whilst in persons of more mature age, felt, or so-called poroplastic jackets, or some of the various forms of mechanical apparatus, will be of most use, for by the use of these the patient may sit, stand, or walk without risk of aggravating the disease. Also, the weight of the head, shoulders, and arms is great in adults, and requires to be taken off the spine by properly devised mechanical means.

As to the period for the application of these various means of securing rest, all that need be said is, that one or more should be employed in as early a stage of the disease as possible. So soon as the existence of an angular curvature is determined, no time must be lost in securing rest and support to the spine.

As to the seat of the disease and the corresponding choice of means, it is difficult to give more than very general rules. But it may be said that when the cervical or upper dorsal spine is affected, mechanical apparatus will be found to be most effective. When the middle or lower dorsal, or lumbar spine is the seat of disease, then the plaster or felt-jacket, according to the age of the patient, will be found to be most useful.

When the recumbent position is had recourse to, it is necessarily, if it can be maintained, the most effective, and should in no case be omitted as an adjunct to other methods of securing rest. It will be found that the prone is preferable to the supine posture, and the patient should, if old enough to understand the importance of rest, be laid upon a properly constructed prone couch. The prone position is certainly the best; for not only is the projecting angle formed by the excurvated spine not injuriously compressed, as it would be in the supine or lateral position, but the patient is more comfortable, and it is easier, should it be necessary, to apply issues or the actual caustery. At the same time, the back not being the lowest part of the body, there is a less tendency to congestion of the spinal veins, and to consequent increase of the inflammatory softening of the bones. Formerly the patient was thus kept in the recumbent position for many months, seldom less than twelve or eighteen, till all the acute symptoms had disappeared. Since the introduction of the treatment by the plaster-jacket to be immediately described, this is no longer necessary. If the symptoms are very acute, the prone couch may be used for a short time, but as soon as possible the plaster-

jacket should be applied, and the patient allowed to move about. When all signs of acute disease have disappeared, and the deformity alone remains, the apparatus shown in the accompanying figure may sometimes be worn with advantage (Fig. 571). It combines three principles in its action—1, a broad pelvic band, forming a firm basis of support round the lower part of the trunk; 2, lateral upright stems, terminating in crutches, by which the weight of the head and shoulders is taken off the diseased spine, and transmitted directly to the pelvic base; and, 3, a posterior plate, which by means of a ratchet can be brought to bear directly upon the excurvated part of the spine, and support, and in some degree rectify the position of this. Taylor's support also (Fig. 572) is an apparatus of great utility, more especially in the advanced stages of angular curvature of the spine, where ankylosis has taken

Fig. 571. — Apparatus for Supporting the Trunk in Vertebral Caries.

Fig. 572. Taylor's Spinal Support.

place between the diseased vertebrae. It has a tendency, in consequence of the upright iron dorsal rods being jointed backwards, to uplift the head and shoulders, and thus often improves considerably the attitude of the patient. But this very advantage in the later stages becomes a source of inconvenience if not of positive danger in the earlier periods of the disease, as it tends to separate vertebrae in process of consolidation. It is of considerable importance that the patient should not be allowed to dispense with proper support too soon, otherwise he will to a certainty suffer a speedy relapse.

Treatment of Diseased Spine by Plaster-of-Paris Bandage.—Lewis A. Sayre, of New York, has very ingeniously applied the plaster-of-Paris bandage to the treatment of caries of the spine with angular curvature. The following is a brief summary of the details of this method of treatment.

The shirt being removed, a thin, closely woven vest without sleeves is put on next the skin. The child then standing under a tripod stand, to the apex of which is attached a block-and-fall arrangement carrying a horizontal iron bar, a padded collar is buckled round the head and chin, while padded stirrups are passed under the arms: straps are then passed separately from the collar and arm stirrups to the iron bar above (Fig. 573). By shortening or lengthening these straps, the relative tension upon the head and arms can be adjusted with nicety. The indication that the proper amount of extension has been made with the pulleys, is the comfort experienced by the patient. He must on no account be raised completely from the ground. When thus

suspended, the spine becomes much straighter; the ears are lifted from the shoulders, and the diseased surfaces of the vertebrae are prevented from pressing upon one another.

A thick towel folded should be placed under the vest, over the forepart of the abdomen. When the case is dry, this is drawn out, and thus space

Fig. 573—Application of Sayre's Plaster Jacket.

Fig. 574—Sayre's Jacket Applied.

is left for expansion of the abdomen during meals. This precaution is a very important detail. Its omission may be attended by very inconvenient consequences.

Plaster-of-Paris bandages are then carefully applied round the body from the pelvis to the arms; and strips of thin perforated tin are placed by the sides of the spine, and a second layer of plaster bandages passed round the whole (Fig. 573). The straps being now removed, the child is laid upon a mattress. As soon as the case is dry, the abdominal pad is withdrawn; and the patient, when erect, is found to be from one to one and a half inch taller. In cases of curvatures of the cervical region, a head-piece is adjusted to the body-case, by means of which the spine may be relieved of the weight of the head. After two or three months, the case may be slit down the front and

fastened with eyelets. After such treatment, it is commonly seen that respiration becomes easy and the circulation free, while symptoms due to irritation of nerves subside. Sayre strongly insists on the importance of practical details, such as the use of loose-textured bandages and suitable plaster, a closely fitting elastic shirt, and, above all, securing a perfect adaptation of the case.

The essential points to be attained by this treatment are: 1st. Moderate extension of the diseased spine by suspension; 2d. Fixation of the spine when so extended in a firm and light casing. The plaster-bandage must not therefore be looked upon as a mere substitute for the ordinary apparatus. It fulfils one indication which the more mechanical contrivance cannot accomplish—by securing moderate extension of the diseased spine at the time of its application. It is more especially in cases of the lower dorsal and lumbar vertebrae that the plaster-of-Paris jacket is so useful.

When the cervical and upper dorsal vertebrae are affected, a special contrivance (Fig. 575) is required to steady the head. A well-made plaster-jacket will last and should be worn for at least six or eight months without change.

Jackets made of softened leather or felt "poroplastic," as they are termed, may be moulded on in the same way—the patient being suspended from Sayre's triangle. They are useful after the plaster-jacket has been discontinued, and have the advantage of being removable for purposes of ablation.

With regard to the value of counter-irritants, such as blisters, issues, moxa, or the actual cautery, much difference of opinion exists amongst Surgeons. For my own part, I believe them to be of little use in any case, to do much harm in many by irritating and weakening the patient, and to be indirectly disadvantageous in all by preventing the application of those mechanical means which are necessary for the rest and support of the diseased spine. Should active counter-irritation ever be employed, it must be used in the earliest stages of the disease. Nothing can be more unscientific or indicate a more profound ignorance of pathology than to use it after abscess has once formed.

The ordinary constitutional treatment that is adopted in strumous diseases must be employed in these cases. Much benefit will be derived from the use of cod-liver oil, iron, the phosphates, and above all good air—country or sea. As in all other cases where bone is diseased, at least three years must be devoted to the cure of a case of angular curvature. But that cure consists only in the preservation of life, not the removal of deformity, which is the inevitable result of chronic ankylosis.

The formation of abscess is best restrained by the continuous employment of rest and support. Should abscess unfortunately form, the danger becomes greatly increased. The questions as to when and how the abscess should be opened will now have to be answered. With respect to the first it may be said that the Surgeon need be in no hurry, but let the abscess come well forward at one point, so that the pus may lie beneath the fascia. It must not be allowed to point.

The danger of opening these large abscesses is two-fold. 1st. It consists in the possibility of putrefaction of the pus left in the cavity, and the con-

Fig. 575 — Apparatus for Disease of Cervical or Upper Dorsal Spine. Plaster Jacket with "Jury-mast." (Sayre.)

sequent development of septic poisoning or pyæmia. With the view of avoiding this Surgeons were formerly in the habit of making vascular incisions, and carefully closing them with harelip pins, so as to prevent the entry of air into the sac of the abscess. Now, however, such precautions are no longer necessary, and by opening the abscess with strict antiseptic precautions and the employment of drainage, the danger of septic infection is greatly lessened. 2d. The more remote danger of abscess consists in the risk of hectic from the long-continued discharge, kept up by incurable bone-disease.

In opening these abscesses an incision should first be made just large enough to admit the finger, which should be immediately passed into the cavity, so that it may be explored for sequestra before the pus escapes, while its walls are still tense. In dorsal or lumbar abscesses the finger may possibly be made to reach the diseased spine, and if a sequestrum be felt loose it might be removed. A psoas abscess should be opened if possible before it leaves the abdomen, by an incision close above Poupart's ligament external to the line of the vessels. If it points at the inner side of the thigh, an incision may be made in that situation as well, but this alone will never drain the whole cavity thoroughly, owing to the narrowness of the sac of the abscess, where it passes beneath the femoral vessels. It has lately been suggested by F. Treves that more direct drainage may be obtained, the diseased vertebrae examined, and possibly sequestra removed by making a vertical incision in the space between the last rib and the ilium immediately internal to the outer edge of the erector spine; this muscle is exposed and drawn towards the midline, the quadratus lumborum may then be cut through close to the transverse processes, the psoas muscle incised, and the vertebrae reached by continuing the operation along the deep aspect of that structure. He recorded three cases in which he had performed the operation with very satisfactory results, in one of which a sequestrum was found loose and removed. In well-selected cases it certainly deserves a further trial. After a lumbar or psoas abscess has been opened for some time, and the discharge reduced to a very small amount, the patient may be allowed to move about with a proper plaster support, through which an opening may be made opposite the sinus for dressing the wound; or a paroplastic or leather support may be made which can be removed when necessary. Antiseptic dressing must be continued as long as any discharge continues.

DISEASE OF THE CERVICAL SPINE.

We have hitherto considered caries as affecting the dorsal and lumbar spine. But the same disease may be developed, though much less frequently, in the cervical region. The reason of its greater rarity here arises from the comparative absence of cancellous structure in the cervical vertebrae, and hence the less tendency to strumous or tuberculous osteitis, the disease probably commencing rather in the ligamentous than in the osseous structures.

The signs are the usual ones of pain, rigidity, and swelling, diffused and indelimited. But there is in the cervical region no tendency to angular excruciations. This is owing to the shallowness of the bodies of the vertebrae and a limiting that coalescence after their destruction which is characteristic of the same disease in the dorsal and lumbodorsal regions. But the patient is unable to support or to turn his head; he holds it in his hands when in the upright position, and rotates the whole body when he attempts to look round. There will be pain on any attempt at movement, whether rotatory or antero-posterior, and on downward pressure on the vertex. Although no

angular curvature can, for the reason just stated, take place in this region, the spinous processes may become irregular, one or two projecting more than the others.

Disease of the Articulations between the Atlas and Axis, and between the Atlas and Occipital Bone, constitutes one of the most serious forms of vertebral caries. In these cases there are pain and swelling, with great difficulty or absolute inability to move the head. Patients affected with this disease present a remarkable as well as a distressing appearance. The sterno-mastoid muscles are remarkably tense and prominent, and the neck being perfectly rigid, they are unable to turn the head, but when they want to look round have to twist their whole body; at the same time, the weakness in the neck usually compels them to support the head with both hands, putting one under the chin, the other under the occiput, and so holding it. The disease may suddenly terminate fatally by luxation of the atlas forwards, compression of the cord, and asphyxia; or more slowly by hectic or gradual interference with the respiratory functions.

Retro-pharyngeal abscess may form as a consequence either of disease of the bodies of the upper cervical vertebrae, or the articulations of the first two. It commences with induration and swelling of the areolar tissue at the back of the pharynx. Subsequently the swelling becomes softer, and fluctuation perceptible. The posterior wall of the pharynx is pushed forwards against the posterior nares, giving a peculiar nasal tone to the voice, and if the abscess be large it may cause difficulty in breathing and swallowing. The formation of retro-pharyngeal abscess in young people should always lead to an examination of the cervical spine. The abscess may burst into the pharynx or may extend outwards, and point at the side of the neck, coming forwards under the sterno-mastoid.

The *Treatment of Disease of the Cervical Spine* must be conducted on the same principles as that of angular curvature, by absolute rest and attention to the general health. The actual cautery may sometimes be of use before suppuration has taken place. When there is much pain it must be applied on each side of the spine at the back of the neck. As great and immediate danger may result from the sudden displacement of the vertebrae and consequent compression of the cervical cord, the head requires to be steadied by proper apparatus, calculated to support and steady its movements. Savary's jacket with the "jury-mast" (Fig. 570) is the most efficient apparatus for disease below the first two vertebrae. In disease of the atlas and axis, the head must be fixed absolutely so that no movement is possible. The patient should be confined to bed in the recumbent position, with a heavy sand-bag on each side of the head. Gentle weight extension by means of a collar holding on the chin and occiput attached to a cord passing through a pulley at the head of the bed is often useful for relieving pain. When the acute symptoms subside, an apparatus, such as is represented in Fig. 331, vol. i., may be applied.

Retro-pharyngeal abscess is a serious complication, for when it bursts into the pharynx it empties itself imperfectly, and decomposition of the discharges ensues, thus perpetuating the disease. To avoid this, J. Clinch, of Edinburgh, recommends that it should be opened early, when possible, by an incision made behind the sterno-mastoid. The carotid vessels and pneumogastric nerve must be pushed forwards without injuring the sheath of fascia in which they are enclosed. The abscess can thus be treated antiseptically. In this way he successfully treated a large abscess containing eight ounces of pus.

OTHER DISEASES OF THE SPINE.

Gummata of the Spine.—Cases of partial destruction of the bodies of the vertebrae by the formation of syphilitic gummata commencing beneath the periosteum have been recorded. The disease closely resembles ordinary caries of the spine in its symptoms, and the diagnosis can be made only by the history, and the coexistence of other syphilitic affections. The treatment is mechanical support in addition to the ordinary internal remedies.

Rheumatoid Arthritis may affect the spine. The intervertebral disks atrophy, and bony outgrowths form from the bodies, which may bridge over the spaces between them. The natural movements are thus restricted. Beyond this, it causes no very definite symptoms, and it requires no special treatment.

Tumors of the Spine.—The bodies of the vertebrae are not uncommonly the seat of secondary cancerous growths. Primary sarcomata also are occasionally met with. The symptoms are pain, usually very severe, localized at one spot in the spine, followed after a time by some excurvation. The tumor projects sooner or later, if the patient survives sufficiently long, into the spinal canal and compresses the cord, causing paraplegia. Except in cases in which the tumor is secondary, the diagnosis from dry caries is scarcely possible. Early supervision of paraplegia, with slight excurvation, in a patient past middle life, would, however, suggest the presence of a tumor.

CHAPTER LI.

DISEASE OF THE SACRO-ILIAC JOINT.

Disease of the Sacro-iliac Articulation is a rare affection. With but few exceptions, systematic writers on Surgery were, until recently, altogether silent upon this subject. Boyer and Chelius mention the disease; but it is only by Nélaton that any detailed description of it has been given. This may be partly accounted for by its rarity, and partly, perhaps, by its having not unfrequently been confounded with some of the varieties of disease of the hip or spine.

Sacro-iliac disease is essentially a chronic affection, lasting for months or years. It appears to be strumous in its origin, partaking of the nature and character of ordinary "white swellings." I have never seen it in young children, and in all the cases which form the basis of these observations it has occurred in young adults from 14 to 30 years old. The exciting causes of the disease are obscure: I have not been able to trace it to blow or injury in any of the cases that have been under my care, although there can be very little doubt that such causes might excite it.

PATHOLOGY.—The disease may commence primarily either in the pelvic bones, or in the articular structures of the sacro-iliac junction. The annexed drawings (Figs. 576, 577), taken from a boy who died of tetanus from the irritation of an issue, six weeks after the commencement of disease in the sacro-iliac articulation, show erosion of the cartilages in patches. The next drawing (Fig. 578), taken from a man about 30 years of age, who died of

this affection after nearly two years of suffering, shows the disease in its most advanced stage. The bones are bare and rough, but not necrosed, they are completely deprived of their encrusting cartilage. There is no deep erosion of them, no cavity, no sign of tuberculous infiltration; no evidence, in fact, of primary osseous disease. The ligamentous structures of the articulations are only partially destroyed. The interosseous ligament was especially in a sound state; it had preserved to a great extent its firmness, and required to be divided with the scalpel in order to expose the interior of the joint and the opposed osseous surfaces. The structures that appear chiefly to have suffered are the synovial and cartilaginous elements of the joint. These are

Sacro-iliac Disease in its early stage.
Fig. 576.—Sacrum. Fig. 577.—Ilium. Fig. 578.—Sacro-iliac Disease, more advanced

normally but imperfectly developed in the sacro-iliac articulation, but may, probably enough, readily undergo disorganizing changes somewhat analogous to those which take place in the so-called "pulpy degeneration of the synovial membrane" in strumous joints.

SYMPTOMS.—The symptoms characteristic of this affection arrange themselves in five distinct groups—viz., Pain, Swelling, Lameness, Alteration in the Shape of the Limb, and Abscess. These we must study separately.

1. Pain. One of the earliest symptoms is a sensation of painful weakness at the lower part of the back and sacrum, increased by movements of the body in walking, stooping, or even in standing, giving the sensation as if the body were falling asunder. The pain is increased by any effort that calls the respiratory muscles into action, such as coughing, sneezing, or laughing, and is greatly aggravated by straining at stool. As the disease advances, the pain becomes more continuous, and of a gnawing or rheumatic character. Its intensity varies greatly; in some instances it is throughout slight, except on movement, in others it is most intensely agonizing, the patient shrieking with agony, and unable to obtain rest in any position. The pain in the gluteal region may in some cases be due to irritation of the lumbosacral cord, which lies in close contact with the articulation. It is accompanied by a peculiar feeling of weakness, of falling asunder, or of want of support in the lower parts of the body. This pain is confined to the gluteal region and groin, and does not extend far down the limb. When the patient is lying on his back or side, the limb on the affected side may be able to

adducted, or the head of the thigh-bone may be pressed up against the acetabulum, without any increase of pain, provided the pelvis be fixed by the pressure of the hands. If this be not done, considerable, even intolerable pain will be experienced on moving the limb. So, also, if the Surgeon seize the sides of the pelvis in his hands, and move them to and fro, or press them together transversely, or separate them by pressing the anterior superior spines asunder, pain will be elicited, the affected joint being then influenced by the movement communicated to it. There is often general and diffused tenderness on pressure over the gluteal region; but this is less about the hip-joint than in coxalgia, and gradually increases as the finger is pressed backwards upon the sacro-iliac articulation, so that it may at last be localized in a small spot.

2. **Swelling.**—A puffy intumescence is perceptible early in the disease, along the line of the affected articulation. It assumes a somewhat elongated appearance from above downwards, and does not extend to any distance outwards under the gluteal muscles, nor does it invade the natural hollow behind the trochanter. As the disease advances, and suppuration takes place, the swelling increases materially, and assumes different and peculiar characters, owing to the formation and diffusion of abscess.

3. **Lameness** is an early symptom. The patient walks insecurely; has a feeling of want of proper support to the body; leans forward, and uses a stick. He puts the foot on the affected side to the ground, but does not tread upon it so firmly as upon the other. He cannot stand on the foot of the affected side, or twist himself suddenly round. As the disease advances, the powers of support and progression diminish, and at last the patient becomes unable to assume the erect position, lying in bed usually on the sound side.

4. **Alteration in the Shape of the Hip and Length of the Limb** is an early and marked symptom. From the very commencement of the disease, the limb on the affected side will seem to be longer than the sound one; the tip of the inner malleolus being usually, as the patient lies on his back, half an inch below the level of the same point of bone on the opposite side. But on close examination, it will be found that the measurement from the anterior posterior spine to the inner malleolus gives the same result on both sides; hence the elongation cannot be owing to any change that has taken place in the bones, or in the three large joints of the lower extremity, but must be dependent on some disturbing cause situated beyond the anterior superior spine of the ilium. On more close investigation, this point of bone is found to be at a lower level, and at the same time more prominent, than its fellow on the opposite side; the displacement is thus produced, not by any obliquity of the pelvis consequent on a twist on the lumbar spine, as in hip-joint disease, but by the tilting forwards and rotation downwards of the whole side of the pelvis; for the displacement which takes place is a double one. The swelling of the affected articulation not only pushes forwards, but rotates downwards, the anterior and superior portion of the ilium; and hence the anterior superior spine is not only at a lower level, but is also more prominent on the diseased than on the sound side. The limb itself usually lies straight, and is wasted and enfeebled.

5. **Abscess** occurs only at a late period of the disease. Many months, a year or more, may elapse before suppuration is fairly established, or, at all events, before the formation of pus is so abundant and so circumscribed that it can be recognized as an abscess. I have observed abscess in connection with this disease in five situations—viz., over the articulation, in the gluteal and in the lumbar regions, within the pelvis, and in connection with the rectum.

The first indication of abscess is met with over the diseased articulation. The puffy swelling which is there perceptible in the earlier stages of the affection, gradually softens, until at last fluctuation is established in it. From this point it may spread outwards into the gluteal region, nearly as far as, but not enveloping, the trochanter; or it may take another course and stretch upwards, forming a considerable accumulation in the loin, upon and just above the crest of the ilium. These forms of sacro-iliac abscess are *extrapelvic*; the other varieties are *intrapelvic*. These latter are of three kinds. In one form the pus passes out of the sciatic notch, and under the great gluteal muscle; in the next it gravitates downwards into the ischio-rectal fossa, and presents by the side of the rectum; and in the third variety which I have observed, the abscess opens into the gut, abundant puriform discharge takes place *per anum*, and, flatus from the bowel passing into the suppurating cavity, a tympanitic abscess results.

PROGNOSIS.—The prognosis of this disease is always most unfavorable. I am not prepared to say that it is of necessity fatal, but I have never seen a patient recover after the full development of the disease, and after suppuration had set in. I have, however, seen a case cured, in which, from the history of the symptoms, the thickening over the sacro-iliac articulations, and the permanent displacement of the side of the pelvis, there was every reason to believe that this disease had existed. But in this instance no abscess had formed.

DIAGNOSIS.—The diagnosis of sacro-iliac disease is important, and not always easy. There are five distinct affections with which it may be confounded—viz., neuralgia of the hip, sciatica, spinal disease, disease of the hip-joint, and disease of the pelvic bones.

1. *Neuralgia of the hip* in young females may readily enough be confounded with the earlier stages of sacro-iliac disease. But the widely spread and superficial nature of the pain in the neuralgic affection, the coexistence of the hysterical temperament, the sex of the patient, and the absence of all limitation of morbid action to the neighborhood of the diseased articulation, render the true nature of the affection sufficiently clear. The obliquity of the pelvis which occasionally occurs in neuralgia of the hip, and causes apparent elongation of the limb, is readily removed when the patient lies on the back; whereas, in sacro-iliac disease, position does not affect the displacement of the limb on the affected side.

2. *Sciatica.* In this affection, the age of the patient, usually more advanced than that of the subjects of sacro-iliac disease; the seat of the pain, below the articulation, and its extent down the back of the limb, the tenderness being in the line of the great sciatic nerve, and not over the articulation, with the absence of elongation, will enable the Surgeon to effect the diagnosis.

3. From *spinal disease*, the diagnosis is usually sufficiently easy; for, although the situation of abscess resulting from caries of the vertebrae may in many cases be the same as that which is occupied by the collection of pus resulting from sacro-iliac disease, yet in caries of the spine, in the vast majority of instances, excurvation of the vertebrae has become prominently marked by the time that the abscess has assumed so great a magnitude as to occupy the inferior lumbar or gluteal regions. In those rare cases in which, as in an instance that was some time ago under my care, caries of the vertebrae, with consecutive abscess, takes place without any angular curvature, it will be found that the patient complains of tenderness on the Surgeon passing the spine opposite the seat of disease; that the spinal column has lost its flexibility, moving stiffly and as a whole; that there is an absence of that elongation of the limb on the affected side, dependent on displacement

of the wing of the pelvis, which is so early observable in sacro-iliac disease; and, lastly, that examination of the sacro-iliac synchondrosis neither elicits pain nor reveals swelling or any of the other signs of disorganization of that articulation.

4. *Disease of the hip-joint* is the affection that is most easily confounded with sacro-iliac disease, and that from which it is of most importance to make the diagnosis. It is especially from that variety of hip-disease which commences in the acetabulum, primarily involves the pelvic bones, and only secondarily implicates the joint, that it is difficult to distinguish sacro-iliac disease; and the importance of effecting this diagnosis is great when we reflect that these cases of hip-disease may be successfully subjected to operative interference, whilst sacro-iliac disease does not admit of relief or removal by these means. The diagnosis between coxalgia in all its forms and the disease we are at present considering may be effected by attention to the following circumstances.

a. The seat of pain on pressure varies. In hip-disease the patient suffers most severely when pressure is exercised deeply behind and above the trochanter in the hollow behind that osseous prominence, or when the compression is exercised against the anterior part of the hip-joint. In sacro-iliac disease, little or no pain is experienced on pressure in these situations; but tenderness is elicited by pressure upon the sacrum and along the line of junction between the sacrum and ilium, behind and altogether away from the hip.

b. The movements that occasion pain are different in the two diseases. In hip-disease, abduction and rotation outwards, or pressure of the head of the thigh-bone into the acetabulum, aggravate the sufferings of the patient to a greater or less degree, often to an unbearable extent. In sacro-iliac disease the thigh may be moved in all directions, ab- or adducted, rotated, flexed, or extended, whilst the patient is lying on the back, without any increase of suffering, provided the side of the pelvis be fixed by the Surgeon. Should this precaution not be taken, the movement impressed on the thigh will be communicated to the diseased articulation, and will necessarily occasion suffering.

c. The signs connected with the alteration in the length of the limb differ in the two diseases. In hip-disease there may be, and usually is in the advanced stages, considerable shortening. This never occurs in sacro-iliac disease.

d. The alteration of the level and of the prominence of the two anterior superior spines, in sacro-iliac disease, may be confounded with that arising from the obliquity of the pelvis usually occurring in the early stages of coxalgia. But here also the diagnosis may be effected by observing that the displacement of the bone in sacro-iliac disease is permanent, and is not influenced by position. The obliquity of the pelvis in hip-disease, giving rise to apparent elongation of the limb, is dependent on a twist in the lumbar spine, which may be rectified by placing the patient on his back, and using a little manipulation. The alteration in the level of the two ilia, in sacro-iliac disease, is not modified by change of position, or by any movement that may be impressed upon the spine.

e. *Disease of the pelvic bones* may of course occur independently of any affection of the sacro-iliac articulation; and when so occurring, it always commences at a distance from the joint—the crest of the ilium, the tuberosity of the ischium, or the acetabulum, being the usual seats of the disease. When it occurs in the first of these two situations, the resulting abscess seldom attains a very large size, and is altogether above or below the synchondrosis, the outline of which can be felt clear and unobscured by swell-

ing of any kind. When the abscesses are opened, the sinuses that result will lead directly down to the rough and carious bone, examination of which will leave no doubt as to the nature of the cases. In these cases, also, no change takes place in the length of the limb, or in the position of the side of the ilium.

When the acetabulum is primarily affected, the difficulty of diagnosis may be greater, in consequence of the large size and often intrapelvic nature of the abscesses, and the coexistence of a certain amount of displacement or elongation of the limb. But here the same circumstances that enable the Surgeon to effect a diagnosis in ordinary coxalgia—viz. the pain in movement influencing the hip-joint merely, and the increased length of limb, as determined on measuring from the anterior superior spine—will prevent his falling into error as to the true nature of this disease.

TREATMENT.—With respect to treatment I have but little to say, and that by no means satisfactory. The treatment must be conducted on the same general principles that guide us in the management of cases of carious diseases of the spine. The great object is to prevent the formation of abscess. If the cure be fortunately accomplished, the patient will probably recover with a limb that, though weakened, is but little impaired in utility; for, the sacro-iliac junction being naturally a fixed joint, it matters little if in the adult, it become ankylosed by disease. Long-continued rest in the prone position; fixing the pelvis, hip-joint, and thigh by means of a large leather cap and splint, or a plaster-of-Paris bandage, which should embrace the whole of the limb from above the crest of the ilium to the sole of the foot; counter-irritation, in the earlier stages, before suppuration has set in (after that has occurred it is worse than useless); the administration of cod-liver oil, iron, and suitable tonics, are the means to be employed. When abscess forms, this must be opened in a suitable and convenient spot, with antiseptic precautions; and the powers of the patient must be kept up by ordinary dietetic means and medicinal tonics, with the view of procuring ankylosis; but, unfortunately, little advantage usually follows the treatment beyond the mitigation of suffering and some prolongation of life. When once suppuration has set in, our hopes of a cure are materially lessened. I am not prepared to state that the affection is inevitably fatal when it has reached this stage, but certainly in the very great majority of instances it is so; the profuse discharge from the large abscesses connected with it inducing hectic, and exhausting the powers of life. No operative interference is admissible.

CHAPTER LII.

DISEASE OF THE HIP-JOINT

HIP-DISEASE presents so many points of peculiar and serious importance, that it is usually, and not improperly, described as a distinct affection, apart from other joint diseases. Like all these it may be acute, subacute, or chronic, and most commonly occurs in strumous subjects; indeed, I think its connection with scrofula is generally more distinctly marked than that of most other affections of the joints. It almost invariably occurs before the

age of puberty. Out of 48 consecutive cases of this disease, of which I took notes, I find that in 16 only did it commence at or after fifteen years of age, and, of those, in 6 cases only it happened above the age of twenty. The collected statistics of cases appear to give a very similar proportion; thus it may be considered essentially a disease of childhood or early youth. It is commonly attributed to slight causes, such as over-exertion in a long walk, a sprain in jumping, a fall, or sitting in the wet.

FORMS OF THE DISEASE.—All the inflammatory affections attacking the coxo-femoral articulation are usually confounded under the term "Hip-Disease" or *Coxalgia*. This is too general an expression; and we shall find included under it several distinct forms of disease that differ from one another in pathology, symptoms, result, and treatment. On looking at the hip-joint in a surgical point of view, we find it to be composed of three distinct parts, viz., the soft structures, the acetabulum, and the head of the thigh-bone. Any one of these may be principally or primarily affected; and we may accordingly divide hip-joint disease into three distinct forms—Arthritic, Acetabular, and Femoral. This division is not purely pathological for in all three forms when the later stages are reached, all the component parts are more or less extensively affected. The distinction is, however, of practical importance, especially in its bearing on the question of excision.

GENERAL PHENOMENA OF HIP-DISEASE.—Before proceeding to describe each separate form of coxalgia in detail, we may consider briefly the conditions which are more or less common to each variety of the affection—viz., Pain, Attitude, Imperfect mobility, Suppuration, Sinuses, Dislocation, and Ankylosis.

1. **Pain.**—The pain in hip-joint disease varies greatly according to the form which the affection assumes. In the more chronic forms of the disease it is at first slight, and, perhaps, referable rather to the knee than to the hip: this is particularly the case in the *femoral* variety, and may be explained by the irritation of the articular branch of the obturator nerve, causing a referred pain to be felt in the terminal branches by the inner side of the knee-joint. Both the hip and knee receive articular branches also from the anterior crural and sciatic nerves. That from the obturator, however, enters the round ligament, and is, perhaps, for this reason implicated early in cases in which the disease commences in the head of the femur.

In the *arthritic* form the pain is always very acute, even intense, seated in the joint itself, and greatly increased by any movement, however slight, of the limb. In the *acetabular* form of the disease the pain is not at first referred to the joint, but rather to the iliac fossa or side of the pelvis; it afterwards becomes severe, gnawing, and deeply seated in the articulation. However slight the pain may be, it is always greatly increased by moving the limb, by pressing the surfaces of the articulation together, or by abduction or rotation. Hence the patient usually keeps the foot raised, and merely supported on the point of the toes, the knee and hip being flexed and adducted.

2. **The Attitude** of the limb is peculiar, and varies in different stages of the disease. In the early stage the limb is usually slightly flexed, abducted, and rotated outwards, or, in other words, assumes the position of natural rest. The cause of this position has been the subject of much discussion. It has been proved experimentally by Bonnet and others, that the limb can be made to assume this attitude by forcibly injecting fluid, so as tensely to distend the capsule. The accompanying figure well shows this fact. It is from a photograph kindly furnished me by A. E. Barker, of a preparation

made by himself. The right hip-joint was forcibly distended with fluid injected through a hole drilled into it through the ilio-spectineal eminence. That the limb may, therefore, assume the position from distention of the capsule by effusion from the synovial membrane cannot be doubted; but in the great majority of cases of hip-disease there is no reason to believe that any such distention takes place.

Fig. 279.—Position assumed by the limb on forcibly distending the capsule of the hip joint with fluid.

That the position is not merely mechanical is shown moreover by the fact that in the early stages of the disease it usually disappears under chloroform. It may, however, be assumed that the position taken by the limb when all the ligaments are tensely stretched by injecting the joint, is also that in which there would be the most perfect general relaxation if the fluid were let out: this position would, therefore, be involuntarily assumed by the patient when the capsule is inflamed. It has also been pointed out by Barker that in full extension "the leverage of the femur acting on the Y-ligament, and the tense anterior part of the capsule as a fulcrum," will force the head of the femur against the acetabulum, and for this reason the patient involuntarily keeps the thigh slightly flexed.

Hilton attributed the position of the limb to a reflex contraction of the muscles surrounding the joint, consequent upon the anatomical distribution of the nerves, it being a rule in all joints that they receive branches from the same nerves that supply the muscles acting directly upon them. According to this view the flexion, abduction, and rotation outwards are due to the stronger muscles prevailing over the weaker.

It has been suggested, also, that the position

may be due to the direct irritation of the flexors and external rotators which lie more immediately in contact with the capsule than the extensors and internal rotators.

When the limb is abducted, if the patient be put in the erect position, the pelvis is tilted in such a way that the anterior superior iliac spine of the diseased side will be found to be somewhat lower than its fellow; at the same time the sound limb is adducted to a degree corresponding to the abduction of the affected side, and thus the two limbs are brought parallel to each other. The knee is flexed, partly on account of the lowering of the side of the pelvis and the flexion of the hip-joint, and partly because by putting the toes only to the ground, the elasticity of the foot is brought into play, and the pain prevented that would arise from the jar of the limb if the patient trod on the heel. The position assumed by the affected limb gives rise to an apparent elongation. Often in these cases of apparent lengthening there is actual shortening, but measurement from the anterior superior spinous process to the inner malleolus on each side shows the fallacy of this appearance.

As the disease advances, the position of the limb undergoes a complete change, the flexion remains and is increased, but at the same time the thigh becomes adducted and rotated inwards, so that the knee is carried against the lower part of the sound thigh. The cause of this position has been the

subject of as much difference of opinion as that of the earlier displacement. In some cases it is undoubtedly due to destruction of the head of the bone and partial or complete dislocation. In these cases it is accompanied by distinct shortening with displacement of the trochanter above Nelaton's line (vol. i. p. 587.). Much more commonly, however, it sets in long before there are any signs of extensive destruction of the head of the bone, and must then arise from other causes. Bosch has suggested that it may be due to the erosion of the upper and posterior wall of the acetabulum, so constantly met with as one of the earliest destructive processes in hip-disease. In consequence of this the head is displaced upwards and backwards, so slightly at first as not to give rise to signs of dislocation, but enough when the ilio-femoral ligament is unsoftened to cause adduction of the limb. The altered position of the limb has been ascribed also to softening and yielding of the thinnest part of the capsule, the posterior and outer, while the inner and anterior part, which is much stronger, retains its toughness; to the external rotators becoming implicated early in the disease, as they lie most closely in contact with the capsule, and thus ceasing to oppose the adductors and internal rotators; and lastly to the position assumed in bed by the patient when the diseased hip becomes too tender to bear any pressure. Probably all these causes are more or less concerned in the production of the adducted position, each acting in a different degree according to the circumstances of the case.

When adduction sets in, the position of the pelvis undergoes a change. In order to bring the limbs parallel and in a straight line with the body, the patient must now raise the pelvis on the affected side and abduct the sound limb, thus giving rise to apparent shortening of the limb on the side of the disease. This may occur without any real, or with very slight, shortening, the amount of which can be ascertained only by measurement.

The displacements of the pelvis and limb are accompanied by corresponding changes in the position of the spine. Owing to the tilting of the pelvis, there is a lateral curve produced in the lumbar region, the concavity of which looks towards the elevated side of the pelvis, and in order to keep the body straight, there is a compensating curve in the opposite direction higher up. At the same time the fixed flexion of the thigh is compensated for by an antero-posterior curvature of the lower spine with the concavity forwards, or, as it is termed, *lordosis*. This conceals the flexion of the hip-joint, so that the two limbs may lie side by side in bed apparently straight, when in reality the diseased hip is flexed to a considerable angle. When the limbs are in this position, if the hand be passed under the lumbar spine, it will be found to be arched forwards, not touching the bed. In order to estimate the amount of flexion, the plan recommended by H. O. Thomas is the best. As the patient lies on his back, the sound limb should be flexed to the full extent at the hip and knee, and pressed upon firmly till the lumbar spine becomes straight, and the hand can no longer be passed between it and the bed; the thigh of the affected limb will then be raised from the bed, and the true angle of flexion becomes apparent. The degree of adduction or abduction is best recognized by putting a tape across from one anterior superior spine to the other, when the angles formed by the limbs with this line are at once clearly seen.

The alterations in length are recognized by measurement from the anterior superior spine to the inner condyle of the femur or the inner malleolus, the limbs being placed as accurately as possible in the same position on the two sides. If greater accuracy is required, the plan described in the chapter on Fractures (vol. i. p. 588) may be adopted. Theoretically real lengthening may occur in consequence of effusion into the joint, but practically the

amount so caused is too small to be recognized by measurement. True shortening may arise from destruction of the head of the bone, dislocation and want of growth. In old cases it is well to measure the tibia separately and to compare it with the sound limb. In this way the proportion of shortening due to general want of growth of the limb may be estimated roughly.

3. **Limitation of movement** is a constant symptom in all forms of hip-disease. The degree of limitation of flexion is ascertained by grasping the side of the pelvis with one hand, while the thigh is slowly raised from the bed with the other. In this way it is easily ascertained how much of the apparent flexion is due to movement of the pelvis and lumbar spine, and how much to true movement in the joint. The degree of possible extension is recognized by the method of ascertaining the angle of flexion recommended by H. O. Thomas. To ascertain the limitation of abduction or adduction, a tape may be passed across the pelvis from one anterior spine to the other and another tape may be held at right angles to this to indicate the normal position of the limb when straight; the limb may then be gently moved from side to side, and the degree of mobility noted. In estimating the possible amount of rotation, the hip and knee must be flexed, and the condyles of the femur grasped and rotated with one hand, while the pelvis is steadied with the other. It may be taken as a safe rule, that if flexion, rotation outwards, and abduction, can be carried to such a degree as to place the limb in the attitude assumed by a tailor when sitting cross-legged, there is no disease of the hip. This position puts the round ligament firmly on the stretch, and if the head of the femur is diseased, would cause considerable pain.

4. **Suppuration** is not a necessary consequence of inflammation of the hip-joint, though in strumous subjects it more commonly occurs than not. We often see the *arthritic* variety run its course without the formation of pus, although occasionally suppuration may occur early with severe constitutional disturbance and great pain. In the *acetabular* and *femoral* varieties, abscess usually forms sooner or later, being the direct consequence of the presence of diseased bone. When the disease commences in the femur, suppuration taking place early with severe constitutional disturbance, is usually associated with more or less extensive necrosis of the head of the bone. In the *acetabular* form, abscess is often one of the earliest signs of serious mischief, sometimes preceding the other signs of hip-disease.

The abscess in disease of the hip usually appears first behind the joint, the pus having escaped from the capsule by perforating the posterior part, which is the thinnest. It then, in most cases, comes gradually forwards beneath the gluteus minimus and medius. Having reached the anterior border of the glutei, it passes beneath the tensor vaginæ femoris, and the upper part of the sartorius, forming a swelling in the upper part of the thigh below the anterior superior iliac spine. From this point it often burrows downwards, and opens behind the thick band of fascia into which the tensor vaginæ femoris is inserted, in the lower part of the upper third of the thigh. Sometimes the abscess appears in front of the joint, though this is rare, owing to the thickness of the capsule in this situation. When the acetabulum is perforated, the abscess forms between the obturator internus and the bone, the muscle being at last extensively destroyed. The pus is confined beneath the pelvic fascia, which becomes greatly thickened, and shuts off the abscess from the general cavity of the pelvis. As the pus increases in quantity, it burrows upwards, and perforates the attachment of the pelvic fascia at the brim of the pelvis, coming to the surface above or under Poupert's ligament. It very rarely escapes by the small scrotic notch along the course of the ten-

don of the obturator internus, and it never reaches the great sciatic notch, being shut off by the thickened pelvic fascia. When there is extensive necrosis of the pelvic bones, the abscess may find its way into the true pelvis, and point beside the rectum; but this is rare in hip-disease. Still more rarely the pus may escape from the front of the joint and get into the psoas muscle, forming a psoas abscess. When this occurs, it is probably due to the existence of a communication between the synovial membrane of the joint and the bursa beneath the psoas in front of the articulation.

5. When the abscesses have burst or been opened, **Sinuses** are left behind, an attentive examination of the position and direction of which is of great importance in forming an opinion as to the seat of the osseous disease. There are three situations in which sinuses are met with, which vary according to their point of origin from the abscess, and the position of the diseased bone. 1. When the sinus opens two or three inches below and a little in front of the great trochanter, about the insertion of the tensor vagina femoris muscle, the disease is almost invariably *femoral* or *arthritic*. 2. When the sinus is in the gluteal region, it may indicate *femoral* or *arthritic*, but not unfrequently is dependent on *pelvic* disease; the acetabulum, or a portion of the dorsum ili, being the part involved. 3. The sinus may open in the pubic region, either above or below Poupart's ligament: in this situation it is almost certainly diagnostic of disease of the *pelvic* bones. When it appears *above* the ligament, it probably leads to intrapelvic abscess: on the other hand, when it opens *below* Poupart's ligament, there is generally disease of the ramus of the pubes or ischium.

It is in fact only by attention to these circumstances that the Surgeon is enabled in many cases to form an approximate opinion on the seat and extent of the osseous disease; for the diseased bone is often so covered in by healthy osseous structure, as when the inner aspect of the great trochanter is affected, or by inflamed and indurated tissues, that the probe cannot touch it: or the sinus may be so tortuous that a straight probe cannot follow its windings. Sacre's vertebrated probe (Fig. 503) is very useful in these cases.

But there is other important information obtainable from an attentive consideration of the situation of the sinuses. It is with reference to the probable nature of the osseous disease. In *femoral* coxalgia, this is almost invariably *caries*—sometimes simple, in other cases tuberculous, and occasionally complicated by necrosis of the head of the bone: hence those sinuses that indicate the existence of primary disease of the upper epiphysis of the thigh-bone prove this to be of a carious nature: whilst, on the other hand, sinuses occurring in the pubic region and by Poupart's ligament are almost invariably dependent on the presence of necrosed bone—necrosis being the form of disease that affects the acetabulum and pelvic bones.

6. **Dislocation.**—In the advanced forms of hip-disease, dislocation of the head of the thigh-bone commonly occurs, and may arise from three causes. a. The joint may be destroyed: the capsular ligament having given way in consequence of inflammatory softening and ulceration, and the head of the bone being thrown out of the cavity by the action of the surrounding muscles. b. *Caries* and partial absorption of the head of the thigh-bone may have taken place, so that it no longer fills up the cotyloid cavity; and the ligaments, and often the upper margin of the acetabulum being at the same time destroyed, it slips out on to the dorsum ili (Fig. 589). c. A fungous mass may sprout up from the bottom of the cavity, and thus tend to push the bone out of it; and, after it has been so extruded, this growth will completely fill the acetabulum.

The occurrence of dislocation is, in the great majority of cases, preceded by the formation of abscess in and around the joint; but in some instances

it happens in consequence apparently of softening of the ligaments, the head of the bone being thrown out of the acetabulum without the supervention of any sign of suppuration. In these cases a false joint may be formed upon the dorsum ilii, where the bone lodges. When it is lying in a suppurating

Fig. 580. — Acute Disease of Hip joint in an Adult. Destruction of Head of Femur. Softening of Ligaments. Dislocation on to the Dorsum Ilii.

cavity it will always be found to be in a carious state, and then no attempt, or at most an imperfect one, is made at the construction of an articulation around it.

Dislocation may take place in any variety of the disease, but it is most common in the *femoril*, in which the head of the thigh-bone is more or less destroyed. In these cases it is usual to find the upper and posterior margin of the acetabulum with which the diseased head has been in contact, extensively destroyed, so that the cavity is enlarged in this direction. In this way the anterior and lower part of the cavity is relieved from the friction of the diseased head of the femur, and is frequently found to be undergoing repair, the surface which has been denuded of cartilage being covered with healthy granulation-tissue. In macerated specimens of this kind the upper part of the acetabulum, against which the diseased head of the femur has been lying, shows the porous, spongy appearance indicative of rarefying osteitis, while the lower part which has been relieved by displacement of the femur upwards, shows evident signs of repair, new bone having been formed, closing up the cancellous spaces, and often rendering the structure more dense than natural. These appearances show that the acetabulum, when affected secondarily, will readily repair in many cases if relieved from the irritation of the friction of the diseased head of the femur against it. When the acetabulum is primarily affected, or extensively destroyed sec-

ondarily, the head of the femur is in some cases dislocated on to the dorsum ilii; in other instances it is not thrown out of the cotyloid cavity, but this becomes at last perforated, and may allow the head of the bone to slip into the pelvis.

7. **Ankylosis** may occur either with or without previous suppuration. If the joint have suppurated and the head of the bone be thrown on to the dorsum ilii, a false joint may eventually form, or osseous ankylosis in a more or less faulty position take place. If the head of the bone continue in the acetabulum without suppuration, osseous ankylosis may ensue with but little shortening of the limb.

PATHOLOGY AND SYMPTOMS OF THE VARIOUS FORMS OF HIP-DISEASE.—It is not often that the opportunity presents itself of examining a hip-joint in the earlier stages of coxalgia before complete disorganization of the joint has taken place. It is impossible, therefore, to define with certainty the exact starting-point of the disease in every case. There is no reason to doubt that the hip-joint is liable to all the various forms of destructive inflammation already described as occurring in other joints. Thus we meet with Acute Arthritis (p. 336), arising in some cases apparently from exposure to cold, in others from acute osteomyelitis and necrosis of the epiphysis of the head, in others from extension of suppuration outside the joint into the cavity of the articulation, and in rare cases from general blood-poisoning, as in pyæmia or puerperal fever. More commonly the disease runs the course of white swelling or strumous arthritis (p. 348), and in the hip as in other joints the morbid process may commence in the synovial membrane or in the cancellous tissue of the bones. When arising in bone, the head of the femur is so constantly the seat of the primary disease, that this variety may be termed Femoral Coxalgia. It must be remembered, however, that clinically it is impossible in these cases to determine the actual starting-point of the disease with any degree of certainty. Thus R. J. Godlee has reported a case in which the disease was running the ordinary chronic course of white swelling of the hip, and was apparently receiving great benefit from treatment when the child died from tubercular meningitis. The examination of the hip showed two small tubercular centres, each forming a cavity about the size of a pea, filled with soft granulation-tissue. One was situated in the growing bone in contact with the Y-shaped cartilage of the acetabulum, and the other in the same tissue between the epiphysis of the head and the neck of the femur. The synovial membrane was injected, and its fringes swollen and becoming converted into granulation-tissue.

Lastly, the hip-joint is liable, especially in adults, to a form of disease which may be termed Pelvic or Acetabular. This commences as inflammation, terminating in necrosis of the rami of the pubes or ischium, the disease subsequently extending to the acetabulum, and thus giving rise to disease of the joint.

Arthritic Coxalgia, Acute Arthritis of the Hip. *Symptoms.*—In this form of the disease the patient is seized with signs of acute inflammation of the joint, coming on rather rapidly, and with great constitutional disturbance and pyrexia. The pain in the joint is most excruciating, accompanied by spasms and twitchings of the limb, and marked by nocturnal exacerbations. The suffering is so intense, that the patient cannot bear the slightest movement of the limb; a fit of coughing, the weight of the bed-clothes, or the shaking of the bed by a person leaning against it, will give rise to the most intense agony; and in the intervals of his suffering the patient is in constant fear of a return of the pain, to which he looks forward with much anxiety.

In these cases the limb is flexed, everted, abducted, perfectly helpless, and motionless: the nates will be found flattened, and there is usually some ful-

ness about the anterior part of the joint, or to its outer side, in the hollow behind the trochanter. There is also, theoretically, true elongation of it, in consequence of the capsule becoming distended with fluid, and pushing the head of the bone downwards, but this seldom, if ever, occurs to such an extent as to be recognizable by measurement. On measuring, in order to ascertain the true length, it is necessary to examine the two limbs together, and to place the sound in exactly the same position as the diseased one; unless this be done, error will very probably creep in, for, on measuring the lower extremity from the anterior superior iliac spine to the lower border of the patella or the inner ankle, it will be found to be of greater length when abducted or extended than when adducted or bent.

In some cases the distention of the capsule with synovial fluid, as the result of the inflammation in the joint, may be so great as to lead to its rupture, and to the sudden dislocation of the head of the bone on to the dorsum ilii, with great pain and much shortening; this, however, is of very rare occurrence, the dislocation seldom taking place until after abscess has formed within the joint, and the articulation has been thus destroyed.

Results.—In this, the arthritic form of hip-disease, various terminations may take place; the result depending greatly upon the constitution of the patient, the nature of the disease, and on the manner in which the affection is treated. In the most favorable circumstances, as the inflammation is subdued, the disease falls into the subacute condition, and recovery gradually but very slowly takes place, with a limb that continues stiff and partially ankylosed, as well as wasted and somewhat shortened from disuse. Sometimes complete ankylosis occurs without the previous formation of abscess. In the majority of instances, however, abscess forms, and then the patient may either be worn out by the continued irritation of the disease, or by the profuseness of the discharge; or great shortening taking place, either by the destruction or separation of the head of the bone or its dislocation out of the acetabulum, the cavity of the abscess may ultimately contract, the sequestra, if any are present, may exfoliate, the carious surfaces heal, and the sinuses close after years of suffering. In the most favorable circumstances, when once the joint has been acutely inflamed, a year or perhaps two will elapse before the patient can use his limb with any degree of security. The safety of the patient depends in a great measure on preventing the occurrence of suppuration. In a certain proportion of cases in which the disease commences with the acute symptoms above described, suppuration rapidly follows in spite of any treatment. In many of these the arthritis is dependent on acute osteomyelitis and necrosis of the epiphysis of the head, and on opening the abscess this may be found as a sequestrum in the cavity of the joint. Such cases are not distinguishable at first from those in which the disease is purely arthritic, commencing in the soft parts. If the patient be very strumous, acute arthritis of the hip, from whatever cause arising, can rarely be prevented from reaching the stage of suppuration, but if the patient be tolerably healthy, and the disease be not due to acute osteomyelitis, suppuration may be avoided, and then recovery may take place with a useful though somewhat stiff and crippled limb. This form of hip-disease is rare in the adult, but should it occur the patient seldom recovers, hectic and exhaustion speedily carrying him off. The lives of children may, however, be saved even in these circumstances; but they will be left permanently lame.

Pathology.—The pathology of acute arthritic coxalgia is the same as that of acute arthritis in other joints (p. 339). Surgeons have referred its origin to all the component parts of the joint. Aston Key believed the round ligament to be very frequently the starting-point of the inflammation, and in the Museum of University College we have a beautiful wax model, supposed to

illustrate the mode of origin; but it is not possible from this to say whether the disease commenced in the ligament itself or in the synovial membrane covering it. Probably all the forms of acute arthritis described as occurring in other joints may occur also in the hip.

Chronic Strumous Arthritis of the Hip. White Swelling of the Hip. Femoral Coxalgia. *Symptoms.*—The disease usually commences very insidiously. It assumes a subacute character, and is chiefly met with in young children. The first symptom that usually attracts attention is, that the child limps and walks in a peculiar shuffling, hopping manner; he does not stand firmly upon both feet, but rests on the toes of the affected limb, the knee of which is bent. The limb will be seen to be everted, somewhat abducted, slightly flexed upon the thigh, with the knee partly bent, and apparently longer than the other. This is, however, apparent, and not real; for on laying the child on its back, it will be found that the pelvis is placed obliquely; the anterior superior spine on the affected side being at a lower level than that on the sound one, and at the same time turned somewhat forwards. Measurement of the limb from this point to the ankle will show that there

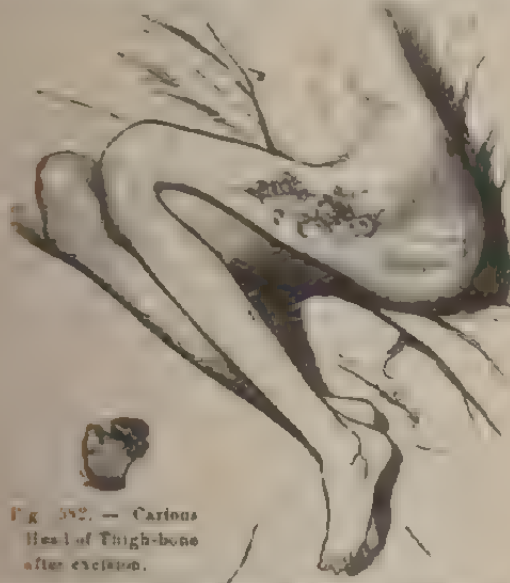

Fig. 382. — Carious Head of Thigh-bone after excision.

Fig. 383. — Chronic Disease of Hip-joint, Stature on outer side of Thigh.

is no alteration in its length. The causes of this peculiar attitude have been already described (p. 443). At the same time that these symptoms are noticed, the child usually complains of pain in the hip, especially on pressing over the front of the joint, or behind the trochanter; this is increased by standing, walking, or any attempt to bear upon the joint; abduction also, and rotation of the limb outwards, or forced extension, are particularly painful, and any concussion of it, as by striking the heel or knee, will greatly increase the suffering. At this stage of the disease, for the reasons already given, the patient will often refer to the knee rather than the hip as the seat of pain, and a careless Surgeon might be misled and treat the wrong joint; the more so, as there is not unfrequently a good deal of cutaneous sensibility about the inner side of the knee-joint (p. 443). Limitation of movement (p. 445) forms

one of the earliest symptoms of the disease. On turning the child upon its face it will be observed that the nates are somewhat flattened, the fold being in a great measure obliterated; and, if it be a female, the labium on the affected side will be seen to be placed at a lower level than on the sound side.

As the disease advances, abscesses may form at any part in the vicinity of the joint. They most commonly occur under the glutei muscles and tensor vaginæ femoris; but sometimes at the anterior part, under the pectineus muscle. When in this situation, they occasionally give rise to very severe suffering down the inner side of the thigh by exercising pressure upon the obturator nerve, which may sometimes become tightly stretched over the wall of the subjacent abscess. In the later stages of the disease the acetabulum is not unfrequently perforated, and the pus then accumulates between the pelvic fascia and the bone, destroying the obturator internus to a greater or less extent, and finally making its way upwards, and pointing at Ponsart's ligament.

It is about this period that the change from the abducted to the adducted position (p. 445) takes place, followed by true shortening of the limb (Fig. 580). The shortening of the limb arises in chronic cases partly from want of growth consequent upon disease, but it is chiefly due in most cases to destruction of the head of the bone, usually accompanied by dislocation upon the dorsum of the ilium. In these cases the remains of the dislocated head can be felt through the thin and weakened muscles in its new situation.

Pathology.—It is very rarely that the opportunity occurs of examining a hip-joint in the earlier stages of coxalgia. By the time the patient dies or, where excision is performed, the ligaments are swollen and softened, the synovial membrane is represented by a pulpy mass of granulation-tissue, the cartilages have more or less completely disappeared, and the denuded osseous surfaces both of the acetabulum and femur are in a state of fungating caries. It seems probable that cases running the clinical course just described, may commence as primary tubercular inflammation of the synovial membrane, or as tubercular caries of the bones secondarily extending to the synovial membrane. The evidence derived from the few cases which have been examined at an early stage, tends to prove that the former is the exception and the latter the rule, and moreover that the bone in which the disease commences is almost invariably the femur. The growing tissue between the epiphysis of the head and the neck, or beneath the articular cartilage, seems to be a common starting point for the disease. The following appearance found in a child about eight years old, who died in University College Hospital of pneumonia, and whose body was carefully examined by Wilson Fox is a good example of the early conditions met with in tubercular arthritis of the hip. The symptoms of hip-disease had existed only about six weeks.

The joint, which, including the acetabulum and capsule, was removed entire, contained a considerable quantity of dirty yellow pus. The ligamentum teres was flattened and covered with spots of yellow lymph; it was much softened, tearing with the greatest ease. The synovial membrane was generally greatly thickened, intensely injected, of color varying from bright red to dull orange, and covered by spots of yellow lymph. The cartilage lining the acetabulum appeared to be healthy, except just around the insertion of the ligamentum teres, where it was softer and more gelatinous-looking than normal for about one to two lines. The cartilage encrusting the head of the femur appeared at first sight to be entirely unaffected.

On making a vertical section through the acetabulum, and the head and neck of the femur, the great trochanter was found unossified, with the exception of a point in its centre, and its connection to the bone was weak and easily torn asunder. The epiphysis of the head was almost completely osseous.

fast; the line of junction being still, however, marked by a band of bluish and very hard cartilage, which extended for about three lines on each side across the bone. In the centre of this, extending both into the epiphysis and the diaphysis, was an eburnated portion of bone, yellow, hard, dense, and compact, these peculiarities being most marked in the portion belonging to the diaphysis. In most parts this mass contrasted strongly in color and in consistence with the reddened cancellous tissue. The encrusting cartilage, though generally appearing healthy externally, could now be seen to be a good deal worm-eaten internally, and indeed, destroyed at one or two points. Where the mass of hard bone came near the surface, the reflection of the synovial membrane was destroyed. Below this, in the neck and the upper part of the shaft, the cancellous tissue was very lax, the walls being very thin, and the medulla filling them extraordinarily red. The medulla at the commencement of the medullary canal, about one inch and a half below the trochanter, was exceedingly red and vascular. Occupying many spots of the cancellous tissue, and also one or two of the reddened medulla, were many little masses of the size of millet-seeds, looking like transparent cartilage, hard and resisting, yielding no juice, not breaking down at all easily under the finger, torn with difficulty by the needle, and when torn showing great numbers of nuclei and fibres. They pervaded the whole bone, and were found also in the acetabulum, but in smaller numbers. Some of them could easily be enucleated where the medulla was soft, others could be separated only with difficulty from the cancellous bone.

From this account it is easy to perceive that the disease was tubercular; that it commenced in the osseous structures, chiefly of the femur; and that it secondarily implicated the soft articular structures.

Acetabular Coxalgia.—In the acetabular form, the disease originates in the pelvic bones, and the articulation and head of the thigh-bone are only secondarily involved. The disease of the pelvic bones has more of the character of necrosis than of caries; but the two morbid conditions are in many cases coexistent, the acetabulum being carious, whilst the rami of the pubes and ischium are necrosed. The soft articular structures speedily become disorganized; the cartilage encrusting the head of the thigh bone is destroyed; the femoral head itself becomes eroded; but the disease does not extend into the neck or trochanters. This form of hip-joint disease is more common in adults than any other variety.

The *Symptoms* are usually obscure in the early stages, but become very unequivocal as the disease advances. There is pain around the hip rather than in the joint itself; this, however, becomes tender on pressure, and the patient cannot bear on the limb, but no alteration takes place in its length, although it becomes greatly wasted. Abscess invariably forms perhaps at first within the pelvic cavity; but it soon presents externally. Sometimes it passes down by the side of the rectum, or through the sciatic notch to the gluteal region; but generally it points near the pubes, under Poupart's ligament. Hectic comes on; the sufferings are greatly increased; and death from exhaustion speedily ensues in this, which is by far the most fatal form of hip disease. In cases of this form, dislocation, though it is met with now and then, rarely takes place. Sometimes, however, the destruction of the acetabulum is so extensive that the head of the thigh-bone penetrates it, and passes into the pelvic cavity. Dislocation is most frequent when the disease has destroyed the head of the bone; so that, the head being no longer present, no impediment is offered to the action of the muscles around the joint, and the bone at length slips from its position in the cavity of the acetabulum.

PROGNOSIS OF HIP-JOINT DISEASE.—The prognosis in cases of diseased hip must be regarded from two points of view—1, as concerns the Life of the Patient; 2, as to the Utility of the Limb that will be left.

1. **Life.**—Disease of the hip-joint, and of the contiguous osseous structures, is dangerous to life in proportion to the abundance and the long continuance of the suppuration; and this is dependent partly on the patient's constitution, but chiefly, and in the first degree, on the extent and nature of the osseous disease. In the *arthritic* form of coxalgia, suppuration is often prevented by rest and appropriate treatment; and when this is the case, the patient will usually recover. If suppuration takes place in cases of this kind, recovery need not be despaired of; but convalescence will be greatly protracted. In such cases much will depend on the patient's constitution. If that be highly scrofulous or tubercular, the prognosis becomes correspondingly bad.

When the bones that enter into the composition of the hip are the primary seat of disease, the case assumes a much graver aspect, but even then, under proper treatment, there is a good prospect of cure. I believe that much will depend on the situation and extent of the caries, and on the question whether it be primary and tuberculous, or secondary to disease of the soft parts-structures. In the latter case the head of the bone, denuded of its encrusting cartilage, softened and carious upon the surface, may be thrown on to the dorsum ilii; profuse and long-continued suppuration will ensue, yet, under good and careful management, and without operation, I have in some instances seen recovery take place.

In those cases in which the disease is primarily *femoral*, and dependent upon tubercular deposit in the head of the thigh-bone, the prognosis is not favorable, for although in a certain proportion spontaneous cure may take place, under proper treatment even without operative interference, a large number die from general tuberculosis or worn out by hectic induced by the long-continued suppuration.

The condition of the *pelvic bones* is one that more materially than any one other circumstance influences the prognosis in cases of coxalgia. When the acetabulum alone of these bones is affected, the prognosis will turn upon whether this acetabular disease be primary or secondary. If it be *primary*, intrapelvic abscess will probably form, pointing above Poupart's ligament; and whether the head of the thigh-bone be dislocated or not, I believe that death must necessarily ensue, unless the diseased osseous structures be excised. If it be *secondary* to disease of the head of the thigh-bone, the condition of the acetabulum need not seriously affect the prognosis. In these cases the head of the bone becomes dislocated, and this very displacement is the first step towards the cure of the disease in the acetabulum. The surface of this cavity, which is roughened, and deprived of its encrusting cartilage, speedily becomes covered by granulations. These become developed into fibrous tissue; and in the course of a short time the whole cavity becomes filled up by a dense fibroid growth, which is in fact the medium of repair of the diseased and disused acetabular cavity.

When the disease extends to the osseous structures around the acetabulum, such as the rami of the ischium and pubes, the body and the tuberosity of the ischium, and the upper lip of the acetabulum, and even the dorsum of the ilium, it usually partakes more of the nature of necrosis than of caries, and is perfectly incurable, except by operation. In extensive pelvic disease such as this, natural means are quite unable to effect a cure, and the patient must die of hectic or intercurrent disease, unless recourse be had to the excision of the head of the thigh-bone and the whole of the necrotic and carious osseous structures.

The report of the "Committee of the Clinical Society appointed to inquire into the value of excision as a means of treating disease of the hip-joint in childhood," contains the most accurate information we possess concerning the death rate of hip disease, in the statistics furnished by Howard Marsh of the cases treated by him in the Alexandra Hospital for Hip Disease in Childhood, between 1867 and 1879. The total number of cases amounted to 401. These may be divided first into 277, or 69 per cent., in which suppuration took place, and 124, or 31 per cent., in which no abscess formed. The following table shows the results. Those classed as "verified cures" were examined by the committee. The value of the statistics is enhanced by the fact that the patients at the Hip Hospital are kept under treatment or watched as out-patients as far as possible until the final result is known. Patients requiring operation are sent elsewhere, and consequently are placed in a separate class.

	WITH SUPPURATION.	WITHOUT SUPPURATION.
A. Verified cures	62	31
B. Reported cures	33	24
C. In progress of cure and still under observation	7	5
D. Untraced		
a. Apparently cured on discharge	9	15
b. Apparently convalescent	9	11
c. In progress on discharge	41	9
F. Indefinite cases	5	7
G. Remained under treatment	14	9
1. Under treatment, apparently incurable	3	0
H. Deaths	87	13
I. Operations	17	0
	277	124

These figures yield a percentage of 42.3 of cures or convalescents, 24.2 of incomplete cases, and 33.5 of deaths. Of the 87 cases in which death took place after suppuration, 16 died of meningitis, 20 died of albuminuria and dropsy, 3 of albuminuria and phthisis, 5 of phthisis, 9 of exhaustion, 2 of erysipelas, 1 of pyæmia, and 24 from unknown causes, 19 of which had been discharged as incurable. In the 13 non-suppurating cases which terminated fatally, death took place from the following causes: 7 from meningitis, 1 from phthisis, 1 from tubercular pneumonia, 1 from croup, 1 from intercurrent disease (nature unknown), and 2 from unknown causes.

In the cases with suppuration ending in cure the average duration of treatment was about 4 years, in the non-suppurating cases it was about 3. In the fatal suppurating cases the average duration of life was 3½ years.

2. *Utility of the Limb.*—When once the bones or ligaments entering into the hip-joint have become inflamed, more or less lameness will invariably result, however carefully conducted the treatment may be. The amount of lameness may consist in a mere stiffness about the hip, a difficulty in abduction, in flexion of the thigh on the pelvis, or in free rotation; or it may extend to absolute uselessness of the shortened, withered, and deformed limb, which hangs powerless from the pelvis, suspended, as it were, by the ilio-femoral ligament, and slightly flexed and adducted. The extent of lameness will depend chiefly upon the form of the disease, and to some extent upon the treatment adopted; but some will ever be left. When the coxalgia is arthritic, and suppuration has not taken place, ankylosis of a more or less complete form will usually ensue; and if the thigh have been kept in the straight position, a sufficiently useful limb will be left, but slightly short-

ened, and possessing free compensating movement in the lumbar spine, enabling the patient to swing it with facility as he walks. If suppurations have taken place, and the head of the bone have been absorbed or dislocated, the limb, even under the most judicious treatment, will be left considerably shortened, weakened, wasted, and more or less adducted, with the knee carried somewhat forwards, as well as inwards, and the patient walking often most imperfectly and with great difficulty on the point of his toes.

Of the 83 cases of cure from the Hip Hospital verified by the committee, 69 are described as "good cures," 11 as "moderately good," and 3 as "cures with considerable lameness."

DIAGNOSIS. In making the diagnosis of coxalgia, care must be taken not to confound it in its early stages with an ordinary attack of *rheumatism*, a mistake that not unfrequently happens. The alteration in the shape and position of the limb, the obliteration of the fold of the nates, and the localization of the pain to one joint, will usually prevent the Surgeon from falling into this error. With *disease of the knee*, care must be taken not to confound hip-disease, in consequence of the pain in the early stages being commonly referred to the former joint; here the absence of any positive sign of disease about the knee, and the existence of all the signs of disease in the hip that have already been noticed, will enable the Surgeon to diagnose the true seat of the affection. *Lateral curvature of the spine*, accompanied by neuralgic tenderness in the hip, occasionally gives rise to apparent shortening of the limb with pain and rigidity, but in these cases the existence of the spinal affection, the superficial nature of the pain, and the absence of increase of suffering when the joint is firmly compressed, or of painful startings at night, will indicate the true nature of the affection. *Abscess* may occasionally, though rarely, form in the vicinity of the hip without that joint being diseased. Should this take place towards the anterior aspect of the articulation under the pectineus muscle, it may, by its pressure upon the obturator nerve, occasion pain in the thigh and knee, as in those cases in which the articulation is affected; here, however, the sound state of the joint at its posterior and outer part, the absence of all obliquity of the pelvis, and of the other signs of the true hip-disease, will enable the diagnosis to be effected. The diagnosis from *sacro-dural disease* has been described at p. 441. In infants *inflammation of the glands in the groin* may simulate hip-disease, as the child flexes and adducts the limb, and screams at any forcible attempt at extension. It can be distinguished from hip-disease by feeling the glands if the child be not too fat, and by observing that the thigh can be completely flexed and freely rotated without causing signs of pain.

Acute hip-disease may be mistaken for *Perityphilitis*. The child lies with the thigh flexed on the abdomen, and complains acutely when the right groin is pressed. The diagnosis is easily effected by anesthetizing the patient, when manipulations of the parts will decide the precise seat of the inflammation.

It may be taken as a general rule that if the thigh can be flexed to a right angle without any movement of the pelvis, perceptible to the hand placed on the anterior superior spine and the neighboring part of the crest, and if while in that position with the knee flexed, the femur can be adducted and rotated outwards till the heel is over the sound thigh, there is no disease of the hip. This movement is so readily made in young children that it is an easy mode of excluding hip-disease, though of course if the movement is impossible, it does not prove its presence, as limitation of movement may be due to causes outside the joint.

TREATMENT.—The treatment of disease of the hip must be conducted with reference to the form of the disease, the acuteness of the attack, and the severity of the local and constitutional symptoms. In all cases, this affection must be managed in accordance with those general principles that guide us in the treatment of inflamed joints.

It is of especial importance to adopt early measures. If we wish to prevent the occurrence of suppuration, dislocation, or ankylosis, the child must, on the supervention of the *earliest* symptoms of impending mischief about the joint, be put under proper constitutional treatment, and complete rest of the limb must be secured by a proper splint. By early attention, a cure may be effected, whereas, if the case be neglected in its first stages, the utmost the Surgeon can do is to save the life of the patient.

When the disease is of the *acute Arthritic* kind, the patient must of course be kept in bed, and absolutely at rest. No treatment will be of the slightest avail, unless we adhere rigidly to that principle which is paramount in the management of all acutely inflamed joints—absolute rest. In inflammation of the hip-joint, there are three methods of securing this: 1, by means of a weight attached to the limb; 2, by the long splint; and, 3, by Thomas's hip-splint.

The particular method employed must depend somewhat upon the acuteness of the symptoms and the position of the limb. As a Thomas's splint requires to be accurately fitted to the limb, and should be specially made for the patient, one of the first two means has usually to be adopted at first. Of the two methods, that by the weight-extension is the best, as it completely relieves the painful startings, and is adapted to all cases, however great the degree of flexion or lateral displacement may be. In applying extension by means of a weight, the following plan should be adopted. The patient is placed upon a hard mattress. The angle of flexion and the degree of abduction or adduction is then ascertained by the methods already described (p. 446), as the extension must at first be made as accurately as possible in the line of the abnormal position the limb has assumed. A long broad strip of adhesive plaster is then applied of sufficient length to reach from a few inches above the knee on each side of the limb, and to leave a loop projecting beyond the sole of the foot for about one foot. In the loop is placed a piece of wood three inches in length to form a spreader, and thus to prevent injurious pressure on the malleoli. A hole may be drilled through the spreader and the plaster covering it, and through this the cord bearing the weight is passed and secured by a knot. Narrower strips of plaster are then applied diagonally round the limb to fix the first piece more securely; great care being taken that no strip passes circularly round the limb in such a way as to constrict it. A flannel bandage is then applied from the malleoli to the middle of the thigh, to insure the adhesion of the plaster. A long splint is then applied to the *sound* limb; without this, although by extension the pain may be removed, adduction or abduction and some degree of flexion cannot be prevented, as the patient will turn on one side and avoid the direct pull of the weight. The long splint being fixed, the weight is applied to the rope passing through the spreader and over a pulley. The pulley should be fixed to some apparatus allowing of its being raised or lowered as circumstances may require. If the proper apparatus, such as is used in hospitals, be not at hand, a pulley may be readily made from a cotton reel with a piece of wire passed through it, by which it can be slung to the back of a chair or a clothes-horse. The weight of the body serves as the counter-extension, and if necessary the foot of the bed may be raised on blocks to prevent the patient slipping down in the bed. The most convenient form of weight is a tin can filled with shot or water, till the degree of extension ob-

tained is comfortable to the patient. The pulley and weight are to be adjusted in such a way that the extension shall act on the limb directly in the line of its abnormal position. To do this the diseased limb must be raised till the lumbar spine is in contact with the bed, and the degree of abduction or adduction must correspond to that noted before the apparatus was applied. During the acute stage any forced attempt to drag the limb immediately into its normal position would only aggravate the pain, but by making the extension as above described, it will be found that the limb speedily falls into the proper position. At the end of each day the pulley must be readjusted so as gradually to bring the limb parallel to its fellow. In recent cases a few days will often suffice to bring the limb into its normal position, in more advanced cases some weeks may be required. If the treatment has to be continued for any length of time, the apparatus represented in Fig. 583 may be employed. In it the pelvis and body are fixed to

Fig. 583.—Apparatus for Extension by Weights in Hip-joint Disease.

the bed by means of broad felt straps and buckles. A leather ankle-strap is then placed round the foot and lower part of the leg, and a padded belt above the knee. From the sides of each of these, straps are carried to a point six or eight inches beyond the foot, where they are attached to a transverse iron rod, four inches long. From this the cord suspending the weight passes over a pulley-frame fixed to the end of the bed. The weight applied should be from two to three pounds in children up to six years of age; four pounds between the ages of six and ten; five or six pounds from ten to thirty.

If the long splint alone be used, it must be applied as for fractured thigh, the perineal band being dispensed with if it causes pain. A single long splint, though moderately efficient in the adult, is of little use in children, as they always manage by twisting the body to maintain a considerable degree of flexion with adduction or abduction. Hamilton's double long splint (Fig. 237, vol. i. p. 594) should therefore be applied, by which much better position is obtained. Weight extension can be applied with this if required. When there is much adduction or abduction, the part of the splint corresponding to the hip-joint on the diseased side may be sawn through and fitted with a hinge, allowing of movement in the required direction, the lower end being at the same time loosened from the cross-bar; the lateral displacement can then be corrected by means of India-rubber bands acting on the lower end of the splint from a nail or peg driven into the cross-bar.

Thomas's splint (Figs. 584, 585) is by far the best apparatus ever invented for the treatment of all forms of hip disease. It may be applied at any stage

and should be worn till the cure is complete. It will, however, often be found most convenient when there is considerable adduction or abduction with acute pain in the early stages of the disease, to correct this by means of the weight extension used as above described before applying the Thomas's splint. Thomas's splint is the only apparatus that maintains absolute rest of the joint, while at the same time the patient is able to move about during the whole or greater part of the treatment. The splint consists of a flat bar of soft iron, varying from three-quarters of an inch to an inch and a half in width, and from three-sixteenths to three-eighths of an inch in thickness, according to the age, size, and weight of the patient. This bar must be long enough to reach from the lower angle of the scapula to the middle of the leg immediately below the prominence of the calf. The upper and lower parts must be straight to fit the back and the leg, and between these it must be bent into a curve accurately fitted to the buttock of the patient. To this

Fig. 584.—Thomas's Splint.

Fig. 585.—Thomas's Splint Applied.

vertical bar, three curved transverse bars of soft iron about $\frac{1}{4}$ inch thick, by 1 to $\frac{1}{2}$ inch, are fixed as in Fig. 584. The upper of these should be of sufficient length to embrace the chest about as far as the nipple on each side. The middle bar should be immediately below the curve for the buttock in the vertical bar. If it be placed too low, the splint is more apt to twist round and allow of flexion. The whole apparatus is padded with a thin layer of

felt, or flannel, covered by leather. The splint is applied in such a way that the curved part of the vertical bar lies midway between the tuberosity of the ischium and the trochanter major. The curved parts are then bent so as to fit the chest, thigh, and leg comfortably. A strong piece of bandage is passed through the rings in the ends of the chest-piece, and tied firmly. A broad body-bandage of swan's down, calico, or flannel, is then wound round the vertical bar, so as to get a good hold of it, and then carried two or three times round the body. A narrower bandage is then applied to the thigh and leg. If the patient is to walk about, braces of strong calico must be fixed to the chest-piece, and carried over the shoulders, otherwise the splint will slip down. If there is much flexion, the splint may be bent forwards immediately below the buttock curve to a degree a little less than that of the limb, which may be allowed to lie upon it with the knee slightly bent. In this position it is secured by a few turns of bandage round the thigh and leg. In a few days, if the patient be kept on his back, the weight of the limb will have extended the hip, so that the whole leg is uniformly in contact with the splint, which may then be straightened a little; and this is repeated until the flexion is corrected. The vertical bar must never be bent opposite the knee. If there is much adduction, it is often convenient to twist the vertical bar, so that its anterior aspect looks very slightly outwards from below the buttock. These alterations in the shape of the splint must be carried out by the Surgeon himself with strong iron wrenches made for the purpose. A little experience is required in the manipulation of these splints, but the necessary skill is easily acquired, and will well repay the Surgeon for the trouble involved in so doing. The splint must be worn continuously day and night till all symptoms have subsided, often for one or two years. In walking with crutches, the patient is raised by a patten on the foot of the sound limb, so that the opposite foot does not touch the ground (Fig. 585). Should suppuration take place, Thomas's splint is still the most convenient apparatus, as it leaves the parts uncovered in which the abscesses point. One great advantage in Thomas's splint is, that under the superintendence of the Surgeon, any common blacksmith can do the ironwork, and any saddle the padding, and it is thus equally available for country or city practice.

Fig. 586—Sayre's Extending Apparatus for Hip-joint Disease.

A very ingenious extending apparatus for hip joint disease, at any period of its development from the earliest to that of abscess, has been invented by Sayre (see Fig. 586). By means of this apparatus, extension is made from the thigh and counter-extension from the pelvis, the apparatus being lengthened by a rack and pinion on the outer bar. It prevents the necessity of confinement to bed, and keeps the limb in a straight position.

After all acute symptoms have disappeared, the joint may sometimes be conveniently fixed by means of a leather splint, the starched bandage, or the plaster-of-Paris bandage. Of these I prefer the starched bandage as being more easily applied. The hip part must be strengthened with a piece of pasteboard lined with cotton, sufficiently long to extend down the whole of the back of the thigh to below the knee, so as to support that joint also, and

the spica bandage must be applied in repeated turns, otherwise the apparatus will not fix the joint. In applying this or any other apparatus, it is often necessary, especially in children, to administer chloroform, as the pain occasioned by the necessary movements may be too severe to be borne without it.

When the disease has from the first been subacute, as is usually the case when it commences in the head of the femur, the same treatment must be pursued, but it may not be necessary at any time to confine the patient to bed, or to have resort to weight extension.

The constitutional treatment must be conducted on those principles already laid down in the chapter on diseases of joints in general.

EXCISION OF THE HEAD OF THE THIGH-BONE AND OF THE HIP-JOINT.

White, of Manchester, in 1769, was the first to propose, and Anthony White, of the Westminster Hospital, in 1821, was the first to perform, excision of the head of the femur. This he did on a boy eight years old, who had had disease of the hip-joint for three or four years, and in whom the carious head of the thigh-bone rested on the *dorsum ilii*. White removed the head and trochanters of the bone, and the patient recovered from the operation, dying of phthisis five years afterwards. The preparation is in the museum of the College of Surgeons. This operation was repeated by Hewson, of Dublin, in 1823; and then seems to have been forgotten in Great Britain until its revival, in 1845, by Fergusson. But in the meanwhile it had not entirely escaped the attention of Continental Surgeons. Oppenheim, in 1829, and Seutin, in 1832, excised the head of the femur for gunshot injury; and, in 1842, Textor published an essay on the subject.

Cases requiring Operation.—Diseases of and about the hip-joint may, so far as the question of operation is concerned, be divided into two great classes—those in which no suppuration takes place, however acute the inflammation may have been; and those in which abscess forms.

To the first class belong those cases in which the synovial membrane is primarily affected with subsequent implication of the cartilages and ligaments. In this form of coxalgia, the patient commonly recovers with a stiffened or even completely ankylosed, though useful and straight limb, dislocation of the head of the bone not having occurred. In such cases, I believe that excision is never needed; at least, I have never had occasion to do it, nor have I ever seen a case that seemed to me to justify such a procedure.

The second class of cases—those in which abscess forms—are by far the most numerous. In the great majority of these, however, the head of the femur is the part primarily affected, and in these recovery will take place eventually, under properly conducted medico-surgical treatment. But the recovery in such cases is always so far incomplete that the limb is left much crippled, and often of but little utility. In cases of this kind, after years of suffering and confinement to bed, and after a hard struggle for existence, we find the unfortunate patient left eventually with a limb that is shortened to the extent of from two to four inches, wasted and adducted, with a projecting deformed hip scarred with cicatrices; the remains of the head of the femur being dislocated from the acetabulum, and adherent to the *dorsum ili* by firm ankylosis. The limb is unable to support the body, and cannot be extended, nor can the sole of the foot be firmly planted on the ground; but the leg is to a certain extent useful in progression, the patient using it as a paddle to push himself on with, as he limps on the point of the toes. In these cases it is interesting to observe how nature compensates for the loss of all abduction and rotatory power in the hip by giving an

extremely increased degree of mobility to the lumbar vertebrae, so that the patient, in walking, swings the pelvis from these, and thus in a great degree makes up for the loss of the natural movements in the ilio-femoral articulation.

But though recovery takes place eventually in the majority of cases of coxalgia that have advanced even to suppuration, yet in some—and not a few—instances the patient's constitution becomes unequal to the drain imposed upon it, and fatal hectic eventually supervenes. This is the direct consequence of the wasting and exhausting influence of the long continued discharge of pus from masses of carious or necrosed bone, too extensive or too deeply seated to be eliminated by natural processes. It is in such cases as these that conservative surgery steps in, and endeavors to save the patient's life by the removal of the morbid cause that keeps up the discharge which is wasting it away. The object here is simply to save life by the removal of diseased bone. For the same reason—the preservation of life from hectic—that the Surgeon amputates in an extreme case of suppurating disorganization of the knee-joint, he excises in an extreme case of disorganization of the osseous structures that enter into the formation of the hip-joint; amputation is here too formidable a proceeding to be undertaken, and yet the removal of the diseased bone, the irritation and suppuration from which are rapidly destroying the patient, is an imperative necessity.

Femoral coxalgia is the form of the disease that is most benefited by operation. In severe cases of this variety, the upper epiphysis of the thigh-bone will be found lying in a state of caries on the dorsum ili, in a suppurating cavity, with sinuses leading down to it. The pelvic bones are sound, the acetabulum is filled by fibrous tissue, though possibly it may be slightly roughened and necrosed at one lip. The soft structures in the gluteal region are thinned and wasted; the limb is shortened and adducted. In such cases as these, the patient will probably perish if left to the unaided efforts of nature; or if he recover, after years of suffering, it will be with a limb shortened, deformed, and but little useful. Resection, being limited to the upper end of the thigh-bone, or at most to the roughened lip of the acetabulum as well, is an easy operation, removes the cause of the wasting discharges and hectic, and in no way increases the already existing shortening, as it is limited to that portion of diseased bone which is already lying above and behind the acetabulum, and which is affected by caries of too extensive and deep-seated a character to disintegrate and crumble away in the discharges, so that a natural cure without operation could take place.

When once suppuration has taken place within the capsule of the joint, the sooner the pus is evacuated the better. No good can possibly come from the retention of pus in the joint. It leads only to further disorganization of the articular structures, to fresh constitutional irritation, and at length to bursting of the capsule, and the formation of large extra-articular abscesses. To Annandale we are indebted for having put this practice to the test of experience, and by making a free incision into the posterior part of the joint in conjunction with antiseptics and good drainage, obtaining the most satisfactory results.

It is only in very acute cases, however, that this treatment can be practised; more commonly the pus forms slowly, and is not recognized till it forms a considerable extra-articular abscess. Such abscesses should be opened early and freely, and, if possible, with antiseptic precautions. At the time the abscess is opened the cavity must be thoroughly examined with the finger to search for sequestra, and to ascertain if possible the situation of the disease, the position and size of the opening in the capsule, and the condition of the head of the bone.

If dislocation have taken place, and the limb consequently have become a good deal shortened or deformed, being perhaps adducted and inverted so far as to be twisted over the other, or drawn up upon the abdomen, much may be done to lessen the deformity by putting the patient under chloroform, bringing down the limb, and fixing it by a proper splint. Ankylosis in a good position may thus be sometimes obtained, and the patient's condition be greatly improved. It is a question whether an attempt at reduction should be made in these cases of consecutive dislocation, as it is very rarely that it would prove permanently successful, the acetabulum being either filled up, or the head of the bone so diseased and lessened in size, that it would not remain in its cavity when put back. Occasionally, however, reduction may be successfully effected. In a woman under my care at the Hospital, with spontaneous dislocation of the hip of about a month's duration, reduction was effected by means of the pulleys, and the head of the bone replaced in the cotyloid cavity, where it remained for some weeks; becoming, however, displaced again in consequence of its being necessary to remove a bandage that was applied, as she became affected with inflammation of the lungs, and could not bear its pressure. If ankylosis be likely to occur, the surgeon must endeavor to secure it with the limb in a straight position; otherwise great inconvenience to the patient may result, especially if it occur in the position represented in Fig. 582. After a stiff joint has formed, the mobility of the lumbar vertebrae, and more particularly of the lumbosacral articulation, will be found to be greatly increased; so that at last the patient will walk with little inconvenience, rotating the pelvis on them. If the ankylosis be not osseous, but the result of the *arthritic* form of the disease, and especially if the head of the bone be still in the acetabulum, the limb may be straightened by forcible extension and rotation under chloroform, and the heel thus brought to the ground.

Excision of the head of the femur has usually been done in advanced cases of the disease; but Annandale, Croft, and others, advise that recourse be had to it in the earlier stages. In those cases of hip-disease in which signs of suppuration are present, they recommend that an antiseptic exploratory incision be made into the joint, and the head of the femur examined; if found diseased, it should be removed by sawing through its neck. Should there be osseous disease beyond this in the acetabulum or in the femur, it must be cut away. Annandale is led to recommend early operation of the kind mentioned in those cases of hip-disease in which signs of suppuration exist, by the consideration that the head of the femur is usually carious in these cases, and that its early removal is likely to check the further progress of the disease, and to leave the patient with a useful and movable limb.

Early excision is required also in those cases in which the head of the femur is necrosed. This condition is not easy to recognize except by digital examination of the articulation from the wound made in opening the abscess. It may be suspected to be present when the symptoms have set in with great acuteness, and have rapidly reached the stage of suppuration, this form of hip-disease being not unfrequently due to acute osteomyelitis of the epiphysis of the head or acute epiphysitis. If the sequestrum is loose, it may be removed in some cases without any further portion of the bone. If it is still attached, the neck may be sawn through, and the head alone taken away.

When dislocation takes place early before the head has been extensively destroyed, giving rise to very marked flexion, adduction and rotation inwards, excision of the bone is often the only means by which the limb can be brought into good position, and in such cases it may be undertaken at an early period.

In the **Acetabular Pelvic** form of coxalgia, the ultimate result is, I believe, inevitably fatal, if the disease be allowed to run its own course unchecked by operation. Large portions of the pelvic bones in and around the acetabulum—such as the tuber and ramus of the ischium, the ramus of the pubes and the dorsum ilii—fall into a state of necrosis: the cavity becomes perforated (Fig. 587); and the head of the thigh-bone, still lying in it, becomes denuded of its cartilaginous investment, roughened and carious as is well seen in the annexed drawing (Fig. 588), taken from a patient of

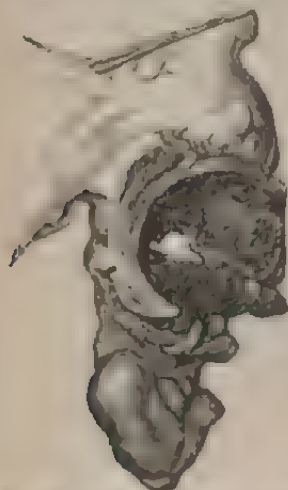

Fig. 587.—Perforation of the Pelvic Bones in Acetabular Coxalgia.

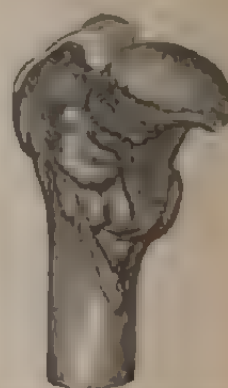

Fig. 588.—Carious Head of Thigh bone in Acetabular Coxalgia.

mine who died of this form of the disease; or it may be dislocated in a carious state on to the dorsum ilii. Large abscesses, intra- as well as extra-pelvic, form, and the patient dies worn out by hectic; the natural efforts of the parts being entirely unavailing to separate and to eliminate such large necrosed masses, deeply lying, and covered in by the upper end of the thigh-bone.

Excision is imperatively required also in those cases in which the acetabulum has been perforated secondarily, in consequence of disease commencing in the head of the femur, as by no other means can the intrapelvic abscess which results be efficiently drained. It is not enough then to remove the head of the femur only; the bone must be sawn below the trochanter, otherwise the upper end of the bone will still interfere with drainage.

Removal of Diseased Acetabulum and Pelvic Bones.—Until a comparatively recent period, Surgeons feared to undertake the removal of large carious and necrosed portions of the pelvic bones, and acetabular disease of the hip-joint was accordingly allowed to run its fatal course unchecked. Hancock was the first Surgeon who undertook the removal of large portions of these bones, and since then the operation has been done several times by others. In no case, has, I believe, more extensive disease been removed with a good result than in a girl who was sent to me many years ago by my friend Mr. Tweed, and from whom I removed the upper end of the thigh-bone, the acetabulum, the ramus of the pubes and of the ischium, a portion of the tuber ischi, and part of the dorsum ilii. This patient, when admitted into the Hospital, was in the last stage of disease, exhausted by

constant discharge, and must inevitably have speedily sunk had no effort been made to remove the cause of the prostration. At the operation she was so exhausted that it was necessary to leave her on the operating-table for some hours before she was sufficiently restored to bear moving into bed. Nevertheless, by the free use of stimulants and nourishing food, she improved rapidly; and when she recovered, the limb presented the appearance in the drawing (Fig. 589); it was straight, shortened about two inches; good movement existed at the hip; and she could walk with much ease. Constitutionally, she was in perfect health, and has continued so up to the time when she was last seen, about fourteen years after the operation. In three other cases I have successfully removed large portions of the acetabulum and of the contiguous portions of the ilium and ischium. In cases such as these, the result, if they are left to themselves, must inevitably be fatal. There is no danger of laying open the pelvic cavity during the removal of these masses of pelvic bone; for, as Hancock has shown during the progress of the disease the fasciæ, muscles, etc., lining the pelvis, become so thickened that they form a barrier which effectually protects the pelvic cavity.

Methods of Operating.—From the preceding considerations, it will be observed that there are two distinct operations practised on the hip-joint. The first is simple resection of a portion of the upper end of the femur, and

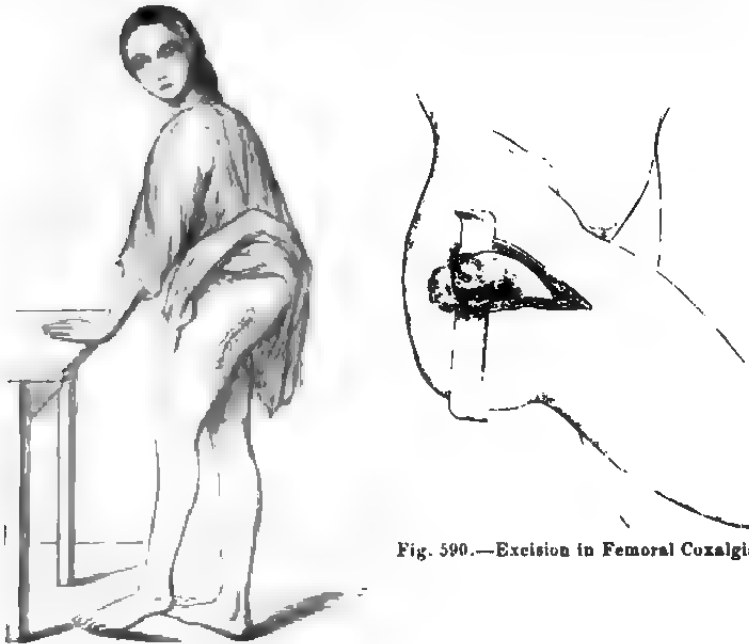

Fig. 590.—Excision in Femoral Coxalgia.

Fig. 589.—Result of Excision for Extensive Acetabular Coxalgia, three years after Operation.

the second, the removal of more or less of the acetabulum, and of the contiguous pelvic bones as well. For the removal of the upper end of the femur only, the following plans may be adopted. The operation may, in most cases, be performed bloodlessly by applying the India-rubber tourniquet in the same way as for amputation of the hip-joint (vol. i., Fig. 9). The

advantages gained by so doing are very great, as it enables the Surgeon to ascertain the condition of the trochanter and upper end of the femur with great accuracy. The patient is then placed on the sound side. If the disease be femoral, the gluteal region perforated with sinuses, and the soft parts thinned, the head of the bone lying dislocated on the dorsum illi, it suffices to pass a director down one of the chief sinuses leading to the carious bone, and to slit this up. If, however, the bone be more thickly covered, and be not easily reached with the probe, and if the sinuses open on the thigh at some considerable distance from the seat of disease, then a T-shaped incision should be made over the upper end of the thigh-bone, so as to expose it (Fig. 590). The limb should now be adducted, rotated inwards, and pushed upwards by an assistant, and the soft structures separated by a probe-pointed knife from around the upper end of the bone, so that the whole amount of disease may come into view. The upper end of the femur is then cut off with a saw, the soft parts around being protected, if necessary, by means of retractors.

There is one practical question with regard to the amount of the upper end of the thigh-bone to be removed, which requires consideration, and that is, Should the bone be sawn through below the great trochanter, or through the neck only, leaving the trochanter? The practice should, I think, differ according to the nature of the disease. If this be femoral, it is best to take away the great trochanter, as the caries has generally reached its cancellous structure, or it may be infiltrated with tubercle. But if the disease be acetabular, and the pelvic bones be the parts most extensively and deeply affected, it will suffice to remove the head only, leaving the trochanter, which is not affected in these cases. After removing the head of the bone, the upper end should be examined, and any carious parts gouged out. The acetabulum must then be examined, and any rough or necrosed bone lying at its edge should be gouged away.

In cases in which the situation and extent of the sinuses leave the Surgeon a free choice for the situation of his incision, the plan recommended by Sayre will be found to give excellent results. A semilunar incision is made with its concavity forwards, commencing above the trochanter major midway between it and the crest of the ilium and carried downwards behind the bone. The first incision must go directly down to the bone through the periosteum. The soft parts are then pulled forwards, and the periosteum divided by means of a small but strong curved bistoury as far as possible round the bone below the trochanter, in a direction at right angles to the lower part of the first incision. The Surgeon then peels the periosteum with the muscles attached to the trochanter off the bone with a strong periosteal elevator. The joint is then thoroughly opened, and the head of the bone turned out by which the periosteum is peeled off from the inner side; lastly, the bone is sawn through above the trochanter minor. By saving the periosteum, Sayre states that he obtains more perfect repair with less shortening, and a stronger and more movable joint.

In some cases the head of the femur may be very conveniently excised by an anterior incision, as recommended by R. W. Parker. The incision should be carried through the interval between the Tensor vagina femoris and the Sartorius. The finger being introduced into the wound passes directly backwards past the anterior border of the gluteus medius and gluteus minimus, and external to the head of the rectus, and thus reaches the neck of the femur. As this is the direction taken by the abscess in a large proportion of cases, no cutting is required after the interval between the sartorius and the tensor vagina has been opened. The neck of the bone may then be sawn through with an Adams's saw (Fig. 598), and the head removed with

sequestrum forceps. This method is adapted to those cases only in which the head of the bone is alone diseased, and it is not necessary to remove the trochanter, and more especially to those in which an abscess is pointing in the situation of the incision. Experience has shown that the wound drains fairly well in most cases, but should there be any accumulation of discharges, an opening can be made behind and a drainage-tube inserted, the anterior wound being allowed to close. No muscles or other important structures are divided in the operation. It should never be attempted when the acetabulum is perforated, as it does not provide efficient drainage for an intrapelvic abscess, and it is not advisable when the head is considerably displaced backwards on the dorsum illi.

In sawing the bone in excision of the hip the ingenious instrument invented by Gowan, of Guy's Hospital, will be found very useful in some cases (Fig. 591).

In the acetabular form of the disease, where large portions of the pelvic bones require removal, the early stages of the operation require to be con-

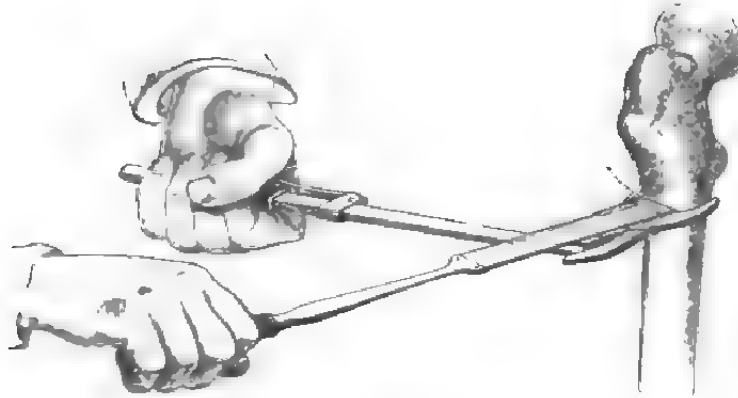

Fig. 591.—Gowan's Osteotome.

ducted in the way just described; the incisions, however, being made more freely, but not carried so far forwards as to endanger the anterior crural, or so far back as to wound the sciatic nerve. After the removal of the head of the thigh-bone, all loose necrosed pieces are to be taken out, and then, by means of ordinary cutting or gouge-forceps, the acetabulum and other carious osseous structures are cut away piecemeal. Those portions of bone which have necrosed are usually lying loose, or else may generally be readily separated by the finger, or by the handle of a scalpel, from the subjacent soft structures; and the muscles and fasciæ lining the pelvic bones, being thickened and infiltrated with inflammatory products, effectually protect the contained parts from all injury.

Excision of the hip should be performed with antiseptic precautions when possible. If foul sinuses exist, these may be scraped with a sharp spoon, and cleaned with a small sponge dipped in a solution of chloride of zinc, and held in a pair of sinus forceps. Some simple antiseptic dressing may then be applied, and the limb fixed with a long splint.

Fergusson recommends that the extension should be made from the opposite thigh, round the upper part of which a socket is fixed, to which the band is attached (Fig. 592). Much advantage will be derived from the use of the bracketed thigh-splint, from which extension may be made by means

of a weight. When the wound has partly healed, if the situation of the incision allows of it, a Thomas's hip-splint may be applied and the patient allowed to move about.

Results.—The result of excision of the hip-joint has to be considered from two points of view: 1. As to the Mortality immediately referable to the operation; and, 2. As to the Utility of the Limb that is left after its performance.

Mortality after the Operation.—Sayre, of New York, in 1860, collected the statistics of 109 cases; of these, recovery took place in 71, 36 died, and in 2 the result is noted as being unsatisfactory. Leisrunk, of Hamburg, has published in the *Archiv für Klinische Chirurgie* 1870 the statistics of 176 cases. In 24 of these, or 13.6 per cent., death occurred from intercurrent

Fig. 522.—Apparatus to be used after Excision of Hip-joint.

diseases—mostly pyæmia (11) and septicæmia (2). Fourteen patients, or 8 per cent., died within a fortnight from exhaustion; 14 others died between this time and the end of the first month—most from exhaustion, one from amyloid disease, and two from phthisis. From the beginning of the second month to the end of the year after the operation there were 27 deaths, or 15.3 per cent.; while 9 died in the course of two or more years, of phthisis and other diseases. Leisrunk states that in 176 cases of excision of the hip, there were altogether 98 deaths. Of this apparently high mortality, however, only about one-half, or 26 per cent. of the whole cases, can be ascribed to the operation itself, or to the intercurrent of pyæmia and other disease which are liable to attend operative procedures. The other half of the deaths were produced by extension of the disease, by diarrhoea, or by phthisis or other disease of internal organs—probably in many instances existing at the time when the operation was performed.

The mortality following the operation appears to have been much lower in England and America than in France and Germany. In 1881 Croft published the statistics of 45 cases operated on by himself, of these 19 recovered, 18 died, and 8 were still under treatment at the time of the report. Of the 40 per cent. of deaths, 15.6 died directly from the operation, 1.4 from some form of tubercular disease, 6.6 from albuminoid disease, and 4.4 from causes unconnected with the joint affection. Of 205 cases of excision collected by the committee of the Clinical Society, 29, or 13.7 per cent., died directly from the operation.

The result of my own experience is, that the mortality directly referable to the operation itself is but small. Excision of the head of the thigh bone or of the hip-joint stands in a different position from similar operations practised on other joints. The Surgeon excises the elbow, shoulder, or ankle, in order to restore a useful limb to the patient. Excision of these joints is a substitute for the loss of the limb by amputation—not, as in the case of the

hip to prevent the almost inevitable loss of the life of the patient by continuance of necrosis.

2. In estimating the utility of the limb left after the excision of the hip-joint, we must compare it with the kind of member that would be left in the event of the patient surviving sufficiently long for a natural cure to result. It would be manifestly absurd to compare a limb which had become seriously crippled, withered, diseased, and shortened, before any operation was undertaken with one in which no morbid process had ever taken place. So also would it be unjust to compare it with the state of a limb left after a slight attack of coxalgia, in which operation could never have become necessary, nor have been contemplated. But, on comparing the results of cases operated on with those of cases which recover spontaneously, after caries and destructive disintegration of the upper epiphysis of the thigh-bone have existed for years, we shall find that the balance is by no means against those in which excision has been done. As I do not consider the operation necessary in cases of *arthritic coxalgia*, I do not compare the result of these cases with that of those operated on, but confine myself entirely to those in which there has been destructive bone-disease. In those rare cases of this description, when, after years of prolonged suffering, recovery is at last accomplished by natural means, the limb left is more or less completely ankylosed at the hip, wasted, shortened to the extent of two to four inches, partially flexed upon the pelvis, adducted, with the knee possibly stiffened, semiflexed, and advanced; the patient is just able to put the toes to the ground, without the power of bearing upon or rotating the limb, but, when he wishes to turn, twisting the whole pelvis by the aid of the greatly increased mobility of the lumbar spine.

After successful excision, the result is much more satisfactory, as may be seen in Fig. 589. The principal abnormal appearance in the limb is its shortening, to the extent usually of from two to three inches—to the extent, indeed, to which the preexisting disorganization and dislocation of the head of the bone had previously reduced it. It is well-nourished, straight, firm, and admits of easy and rapid progression. The ankylosis is fibrous, not osseous. The patient is thus enabled to flex the thigh on the pelvis, and to abduct it, but, just as in cases that have undergone a natural cure, the power of external rotation and of abduction is lost, the mobility of the lumbar spine compensating for the loss of these movements.

DISEASE OF THE GREAT TROCHANTER occasionally occurs with abscess in the upper and outer part of the thigh, at first sight closely resembling hip-disease; but a little careful examination with the probe and by manipulation of the limb, will soon convince the Surgeon that the joint is free from disease, and that the morbid process is limited to the trochanter, and possibly the root of the neck of the thigh-bone. Disease of the trochanter is more common in children, but is occasionally met with in adults. The most common pathological condition met with is necrosis either central or superficial. In children this may be the result of injury or of acute idiopathic osteomyelitis of the epiphysis of the trochanter. Tubercular caries sometimes occurs also in this epiphysis just as in that of the head of the bone. In these cases the limb should be made bloodless, and the trochanter freely exposed by a curved incision (Fig. 591). Sequestra may then be removed, or the diseased osseous structures gouged away. In such operations I have not only successfully removed the greater part of the trochanter, but have scooped out even a portion of the interior of the carious neck of the thigh-bone at its trochanteric end; thus preventing the inevitable disorganization of the hip-joint which would have resulted if the diseased bone had been allowed to remain in close proximity to the articulation. In this operation the Surgeon neces-

easily comes into very close proximity with the capsule of the joint; and unless great care be taken this may be opened, and thus the very mischief induced which the operation is undertaken to prevent. Should the disease be found to be so extensive that it becomes necessary to excise the joint, it can be easily done without extending the incision.

AMPUTATION IN CASES OF DISEASE OF THE HIP-JOINT.—The question of amputation in cases of disease of the hip-joint is one that must often have presented itself to the Surgeon when he has contemplated the shortened, wasted, and deformed member that is frequently left after the more ad-

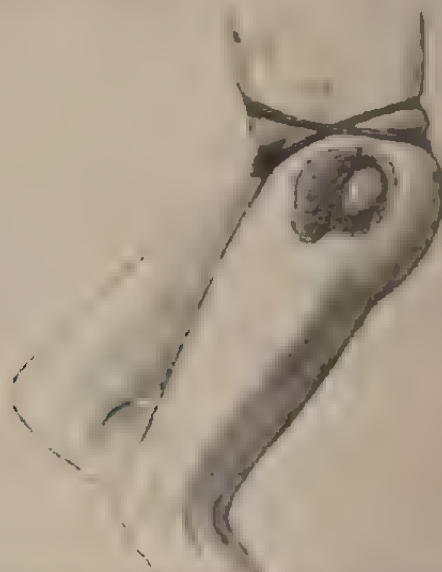

Fig. 163.—Incision exposing the Great Trochanter for the removal of diseased bone.
Remarch's bandage applied to render the operation bloodless.

vanced forms of the disease, and which can never be rendered useful as a basis of support to the body by any mechanical contrivance, however skillfully designed, but must always remain not only a useless, but a cumbersome appendage.

It appears to me that in the more advanced chronic cases of hip-joint disease, this operation is justifiable, and, indeed, is to be advocated in certain circumstances. These are as follows:

1. In cases where the disease is confined to the head of the femur, or where, if any portion of the pelvic bones be attacked, it be to so limited an extent as to be readily removable by the gouge, excision would necessarily be the usual practice. But if the patient's health be too low to bear this, or if the limb be so shortened, atrophied, and deformed by long disease as to be incapable of furnishing proper support to the patient, then amputation at the hip-joint would, I think, be a proper procedure. I do not think that the mere destruction of the cartilaginous lining of the acetabulum should militate against the performance of the operation; for we constantly see in hip-joint disease when the head of the bone has been dislocated, or after amputation at the hip-joint for accident or ordinary disease, that the acetabulum fills up with a dense fibroid mass after the destruction or removal of its car-

ilage. But, if the pelvic bones be so far diseased that the necrosed or carious part does not admit of removal, then necessarily amputation would not be justifiable.

2. When the disease involves the shaft of the femur, which may be necrosed, or atrophied to such an extent as not to leave a sound limb after the removal of the upper epiphysis, amputation would be proper.

3. Amputation would be justifiable after excision has been tried and has failed in securing a useful result to the patient, the limb being left short, weak, loose, and cedematous.

4. In a few cases amputation has been successfully performed when, after excision, the discharge from the sinuses had continued, and albuminoid degeneration of the viscera had set in. Cases have been recorded by Marshall and Barwell, in which, after the operation, the size of the enlarged viscera sensibly diminished, and the general health greatly improved.

5. Excision of the hip is occasionally followed by osteomyelitis of the femur, and acute necrosis of the shaft. Should the patient survive till the process becomes chronic, amputation affords the only chance of life. The operation was successfully performed under these circumstances a few years ago in University College Hospital.

ANKYLOSIS OF THE HIP-JOINT.

Ankylosis of the Hip-joint, following its inflammation, differs in its degree of completeness and in the position of the limb. Thus, it may be fibrous or osseous; or the limb in either of these cases may be straight, or more or less flexed on the abdomen or adducted.

The most important point in all these cases is the *direction of the limb*. If that be straight, but little treatment is required, or indeed possible. When the head of the bone is completely ankylosed with the limb in this direction, the osseous structures of the head of the femur and of the acetabulum being fused together, absolutely nothing can be done to improve the patient's condition. The lumbar spine will acquire increased mobility, especially in a rotatory direction, and the patient will stand and walk with ease. The chief difficulty arising from the position of the limb will occur in mounting stairs and in sitting.

If, however, the ankylosis be not complete, but fibrous, even though the limb be straight, the freedom of movement may be much increased, and any faulty direction as to abduction or adduction may be in a great measure remedied, by douches, friction, pressure, or even forcible movement, and occasionally by the subcutaneous section of tense bands of fascia, or of tendinous and muscular structures about the anterior superior spine of the ilium.

If, unfortunately, the limb have become ankylosed in the flexed or angular position, means must be adopted to straighten it; and this must be done whether the ankylosis be fibrous or osseous. For here the deformity and inability of the limb are always considerable; and increasingly so, the more the ankylosis approaches to a right angle.

In rectangular ankylosis of the hip, the foot cannot be put to the ground so long as the spine is straight (Fig. 594). In order that the toe should touch the ground, it becomes necessary that the body be bent forward; and the lumbar spine will consequently be thrown into a very considerable arch with the convexity forwards (Fig. 595).

The extent of the angular deformity in this kind of ankylosis can always be easily measured in the following way. If the patient be laid flat upon his back, so that the lumbar spine touches the mattress on which he is lying,

the knee will be raised above that of the sound limb, and the angle formed between the thigh and trunk will be at once very perceptible. But if the knee be depressed so as to be brought to the same level as that of the sound limb, then the anterior superior spine of the ilium is rotated forwards, and the lumbar spine arched forwards to an extent proportionate to the angle of deformity.

This angular ankylosis of the hip-joint requires to be corrected, and the limb to be brought into a straight position, so that, even if it be shortened, the patient may, by means of a high-heeled boot, rest it upon the ground, and use it as a means of support and of progressing. This may usually be effected without much difficulty, when the ankylosis is fibrous, by forcible extension under chloroform, the limb being thus often brought straight at

Fig. 394.—Ankylosis after Hip-joint Disease;
Flexion of Limb on Pelvis.

Fig. 395.—Ankylosis after Hip-joint Disease;
Curvature of Spine in posing
Foot on Ground.

once without any material difficulty. But in other cases this cannot be done by simple extension, resistance being offered by the muscles on the anterior and upper part of the thigh. In such circumstances, those that offer most resistance must be divided subcutaneously; and these will usually be found to be the rectus, tensor vaginæ femoris, pectineus, and gracilis. After the limb has, in this way, been straightened, and maintained for some time in the straight position by means of the long splint or weight apparatus or Thomas's splint, means may be adopted by passive motion and frictions to restore the mobility of the joint.

Operation for Osseous Angular Ankylosis.—When osseous ankylosis of the hip has occurred in the flexed position, the case necessarily becomes much more serious; and the rectification of the position of the limb, and its restoration of its mobility, can be effected only by surgical operation.

The operation by which these objects are accomplished consists in the division of the Upper Part of the Femur; through its neck, if any remains of that structure still exist, or, at all events, above the trochanter minor.

The first operation of the kind was performed by Rhea Barton, in 1826. It was done in the case of a sailor, 21 years of age, who, in consequence of an injury, had an osseous ankylosis of the hip in a nearly rectangular position. Barton, according to Gross, made a crucial incision over and down to the great trochanter. The muscles were detached and turned aside, and the

bone sawn through, the great trochanter and part of the neck of the femur being divided transversely. Whether a simple section of the bone was made, or, in conformity with Barton's usual practice in ankylosis, a V-shaped piece of bone was removed, I know not; for on this point American authorities differ. But the limb was brought into a straight position, and put up in a fracture-apparatus for twenty days. At the end of this time, passive motion was commenced, and at the end of four months the patient had a movable false joint, so that he could rotate the limb, abduct it for twenty inches, and carry it backwards and forwards to a still greater extent. The case was therefore eminently successful. The operation appears, however, to have attracted but little notice, and to have been but rarely followed by others. It is true that Barton himself operated a second time; and that Rogers, of New York, in 1830, did so successfully on a man 47 years old. The example of these American Surgeons was followed in Europe, by Textor in 1841, and by Maisonneuve, in 1847, on a girl of 18, successfully. Ross (U. S. A.) operated in 1857, on a woman of 23. In the two latter cases no false joint was made; but the bone, after being straightened, united again by callus. In March, 1869, I performed a similar operation at University College Hospital, on a girl of 16, who had rectangular osseous ankylosis of the right hip-joint. The patient made a slow but a good recovery with a straight and useful limb. There was no attempt at the formation of a false joint, but consolidation took place at the line of section.

The operation, having a double object in view, viz., the rectification of the position of the limb, and the establishment of a mobile false joint near to the obliterated ilio-femoral articulation, was thus shown to be practicable; yet it had scarcely taken a place in surgical literature or practice, until Sayre, of New York, in 1862, by performing it in two cases successfully, brought it prominently before the Profession, and thus led to its establishment as a recognized operation for the remedying of these deformities. Sayre is undoubtedly entitled to the great merit of having established the operation on a distinct principle. His object was twofold; first, to go above the trochanter minor in the section of the bone, so as to retain the attachment of the psoas and iliacus muscles to the shaft for the purpose of flexion; and secondly, by cutting out a semicircular piece of bone, with its convexity upwards, and then rounding off the upper end of the lower fragment, more nearly to imitate the natural shape of the joint, for the purposes of motion and to prevent slipping of the bones. Fig. 596 shows the situation and shape of Sayre's section, and of the piece of bone that he removes. The section of the bone is effected after its exposure, by means of the chain saw; the transverse section being first made, the convex one next (Fig. 597).

W. Adams has devised a much more simple operation, having in view the same objects. His plan is to divide the neck of the thigh-bone *subcutaneously* about its centre. This idea he put in practice in December, 1869, when he performed the first subcutaneous section of the neck of the femur for the relief of deformity resulting from angular ankylosis. This operation is done as follows. A tenotome, having been introduced a little above the top of the great trochanter, is carried straight down to the neck of the femur, dividing the muscles and opening the capsule freely. The knife being withdrawn, a saw of this size (Fig. 598), set in a strong handle, is

Fig. 596.—Lines of Section in Sayre's Operation for Ankylosis of Hip-joint.

passed down to the bone, which is cut through from before backwards (Fig. 597). The section of the bone takes a few minutes, and is as much an art of filing as of sawing. The wound is then closed by a pad, and the limb brought straight. Before this could be done in Adams's first case, it was

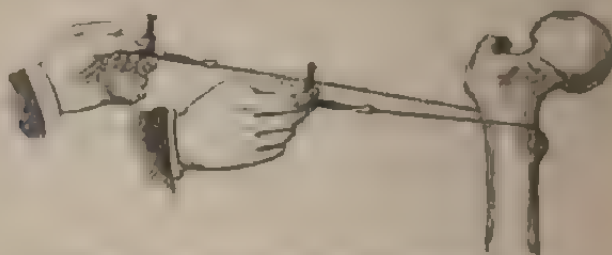

Fig. 597.—Application of Chain Saw in Sayre's Operation.

necessary to divide the long head of the rectus, the adductor longus and the tensor vaginæ femoris muscles. In performing this operation, as Adams justly observes, it is of great importance for the Surgeon to bear in mind the altered direction of the shaft of the femur, which is usually adducted as well as flexed forwards, so that the division of the neck may be made at

Fig. 598.—Saw used in Adams's Operation.

Fig. 599.—Application of Saw to Neck of Thigh-bone in Adams's Operation.

right angles to the axis of the bone and not obliquely, or in a direction more or less parallel to the shaft. After the operation in Adams's first case, an endeavor was made by passive motion to get a false joint, but this being unsuccessful, the attempt was abandoned, and the limb allowed to ankylose

in the straight position. Since this case, the operation has been repeated successfully by Adams and by many other Surgeons.

Maunder preferred a chisel to the saw in practising osteotomy of the neck of the femur, and had much success in the operation so performed.

On comparing this operation with those which had preceded it, by Barton, Sayre, and others, there can be no doubt of its superior simplicity and safety; and although it is perhaps less likely to be followed by mobility of limb than when a piece of bone is cut out by Sayre's method, yet it must be admitted that not only is a movable false joint of doubtful utility, but it seems to have been very difficult of establishment, so great is the tendency to bony ankylosis after these sections.

Cross- or Scissor-legged Deformity is occasionally met with as the result of ankylosis of the hip-joints. Fig. 600, which Clement Lucas has allowed me to take from one of his cases, illustrates admirably the peculiar positions assumed by the lower extremities in this remarkable deformity. Its mode of origin is somewhat obscure. The view to which Lucas inclines is probably the correct one, viz., that it is due to a gradual, probably unconsciously developed action on the part of the patient, with the object of placing the limbs in the most favorable positions for progression. One leg is usually affected first—after a time the other follows. Progression is from the knees not the hips. The two limbs usually become equally affected—but in a case that I saw with Tyson, of Folkestone, the left was crossed over the right, the latter being nearly straight. Should it be thought desirable to attempt to correct this deformity, an anæsthetic should be given, and if the ankylosis is not perfect, the adhesions must be broken down and the limbs straightened. If the ankylosis is osseous, the neck of the femur on either side must be cut across with saw or chisel, and the limbs brought into position.

Fig. 600.—Cross-legged Deformity. Lucas's case.

CHAPTER LIII.

DISEASES OF SYNOVIAL MEMBRANES, AND OF MUSCLES.

DISEASES OF BURSE.

THE bursæ which naturally exist, either under the skin, beneath the muscles and ligaments, or around tendons, are subject to various diseases. These sacs are sometimes developed from continued friction in situations where they are not naturally met with; thus, for instance, bursæ have been found at the projecting point of a hump-back, on the prominent parts of club-feet, or at the extremity of a stump. These abnormal bursæ also may become diseased.

Situations in which Bursæ exist.—Bursæ are either deep-seated or subcutaneous. The deep bursæ are as a rule more perfectly developed, closely resembling true synovial sacs, and in many places communicating with the cavity of a neighboring articulation. The subcutaneous bursæ, situated over prominent bony points, appear to be little more than enlarged areolar spaces, and are in most places acquired after birth as the result of friction. The following are among the most important situations of the bursæ. On the front of the neck, according to Verneuil, there are three bursæ, one in front of the *pomum Adami*, one in the thyro-hyoid space, extending to the under surface of the hyoid bone, beneath the sterno-hyoid muscles, and another above the hyoid bone between the genio-hyoid and genio-hyoglossus muscle of the opposite sides. Beneath the deltoid and the acromion process is a large bursa, often communicating with the shoulder-joint. In the neighborhood of the elbow are a large subcutaneous bursa over the olecranon, and a small one between the biceps tendon and the bone immediately above the insertion of the muscle. In the neighborhood of the hip are three bursæ about the great trochanter, a large one between it and the *gluteus maximus*, and two smaller sacs between the smaller *glutei* and the bone. Another bursa of considerable size lies over the tuberosity of the ischium. In front of the joint is a bursa beneath the *psoas* and *iliacus* muscles, frequently communicating with the cavity of the articulation. In the neighborhood of the knee there are two bursæ in front, the bursa *patellæ* between the deep fascia and the bone, and that beneath the *ligamentum patellæ*, between it and the upper part of the tubercle of the tibia. Occasionally the upper part of the synovial pouch of the knee, is shut off from the general cavity of the joint, and forms a separate bursa beneath the *extensors*. In the ham there is a large bursa between the inner condyle of the femur and the *gastrocnemius* which frequently communicates with the joint, a similar smaller bursa on the outer side, another between the biceps tendon and the external lateral ligament, and others beneath the *semi-membranosus*, the *popliteus*, and the *sartorius*, *gracilis*, and *semitendinosus*—between these muscles and the bone. At the heel there is a large bursa between the *tendo Achillis* and the *os calcis*. The above bursæ are all well-developed and constantly present, and are those most liable to disease; but, in addition to these, a number of less perfectly formed subcutaneous sacs are met with in all parts of the body. The most important of these are in the following situations: behind the angle of the lower jaw, on the symphysis of the chin; on the acromion, the external and internal condyles of the humerus, the styloid processes of the ulna and radius; on the dorsal surface of the *metacarpophalangeal* articulations, and on the dorsal aspect of the *phalangeal* articulations; on the anterior superior spine of the ilium; on each condyle of the thigh-bone, the tuberosity of the tibia, the two malleoli, the dorsal aspect of the toes, and on the plantar aspect of the heads of the first and fifth metatarsal bones.

Morbid Alterations.—The continued irritation of bursæ by the pressure that is exercised upon them, may cause them to inflame, to enlarge, to become thickened, or to undergo various other changes in structure. This enlargement of the bursæ in particular situations is often connected with special employments, by which continuous and severe pressure is exercised upon certain parts of the body; thus frequent kneeling will occasion enlargement of the bursa *patellæ*, hence called "housemaid's knee;" miners are occasionally subject to an enlargement of the bursa lying over the olecranon, hence called "miner's elbow" (Fig. 601); and weavers to the same condition in that over the tuberosity of the ischium, giving rise to "weaver's bottom."

The five following pathological conditions may occur in the burse in any part of the body:

1. The bursa may, in consequence of continued pressure or irritation, become simply enlarged and filled by the excessive secretion of a clear, straw-colored serous fluid.

2. Inflammation may take place in the bursa with or without previous enlargement. The inflammation so set up speedily runs on to suppuration; and, when the tumor is opened, fluid, consisting of an admixture of the bursal secretion and pus, escapes. The bursa, when its contents have suppurated, may either give way externally, pointing like an ordinary abscess,

Fig. 601.—Enlarged Bursa over Olecranon—Miner's Elbow.

and the integuments covering it sloughing; or, the pus may escape subcutaneously beneath the deep fascia, and form a widely spreading abscess around the part.

3. The enlarged bursa may contain a dark fluid, usually of a brownish color, with a large number of small, flattened, elongated bodies of about the size of grains of rice or of melon-seeds, floating in it. These bodies are of a fibroid structure, and their mode of origin is not certain. They have been supposed to be formed in some cases by a fibrinous exudation into the cavity of the bursa, their peculiar form being the result of the movement of the part. In other cases they have been supposed to arise from villous growths similar to those observed in the synovial membranes of joints. That they may be formed from extravasated blood also seems probable from the fact that S. G. Shattock has discovered crystals of hæmatoidin in some of the specimens in the museum of University College. The fluid is sometimes found to contain cholesterine.

4. The wall of the bursa may gradually become thickened by a growth of dense fibroid tissue, until the tumor becomes perfectly solid, or at most contains but a small cavity with a little serous fluid in its centre. The section of a bursa thus solidified presents a laminated or foliated appearance.

5. Occasionally in gout, burse may become the seat of a deposit of urate of soda. This is most commonly met with in the bursa over the olecranon.

The symptoms of the diseases of burse in general will be best studied by considering them as they occur in the bursa patellæ, which, from its exposed situation, and its liability to injury, render it more prone to become diseased than any other similar structure in the body. I shall, therefore, first describe the symptoms and treatment of that bursa, and subsequently briefly allude to the similar morbid conditions in some of those situated in other parts.

DISEASES OF THE BURSA PATELLÆ.—The various affections to which the bursa is liable, may be divided into two classes: 1. Inflammatory affections, and, 2. Enlargements, of a fluid or of a solid character.

1. Inflammatory Affections.—This bursa is frequently the seat of *Simple Inflammation*. Undue pressure in kneeling upon a hard, irregular, and cool surface, such as stone, is likely to excite inflammation; hence its frequency in housemaids, whose occupation obliges them to kneel a great deal on floor and stone steps; and hence, also, the common title of "housemaid's knee," given to this and to many other affections of this bursa. But this disease, although frequent among housemaids, is not limited to them; for it occurs in females following other occupations, and in men as well as in women.

In simple inflammation, however occasioned, the bursa becomes rather suddenly swollen, tense, red, and hot, with some fluctuation deeply under the integuments. The swelling, heat, fluctuation, and redness of a dusky color, all situated in front of the patella, point out the nature of the affection.

The *Treatment* of this inflammation is simple enough. Leeches, followed by evaporating lotions, and keeping the patient at rest, are the means to be employed. Under this treatment, the disease will frequently undergo resolution in the course of a few days. It may, however, go on to suppuration, and, in rare cases, to disease of the patella itself, or sloughing of the bursa.

Suppuration of the Bursa occurs in perhaps the majority of cases of acute inflammation. This is a matter of great consequence, because the accumulation of pus, being of large size, and tending to diffuse itself around the knee-joint, is liable to be mistaken for abscess in that articulation. Sometimes it will point, and the pus discharge itself externally in the usual manner; but very generally it gives way subcutaneously, invariably to the outer side of the sac, and its contents speedily diffuse themselves widely around the joint beneath the fascia lata.

The history of the case affords the means of diagnosis. In suppuration of the bursa patellæ, the abscess commences by a superficial swelling and inflammation in front of the knee, which, after a time, extends laterally, enveloping the joint, the fluid gravitating on each side, but more especially on the outer one, nearly as far, perhaps, as the hamstrings. There will have been none of the signs indicative of acute arthritis accompanying the formation of this large abscess; no startings of the limb, no laxity or pain in moving the articulation, no grating of the articular ends; and little, if any, constitutional disturbance. The movements of flexion and extension of the joint are free up to a certain point, where they are checked by the mechanical obstacle of the purulent accumulation. But the most important diagnostic sign is the relation of the abscess to the patella. In a suppurating bursa the patella is invisible, being covered by the fluctuating swelling. In effusion, whether synovial or purulent, into the joint, the patella is above, floating upon the fluid.

The *Treatment* of this condition is simple enough. A free incision must be made to let out the pus, and this should be done if possible before the abscess has extended beyond the natural limits of the bursa. The incision is usually made in the middle line, but better drainage is obtained, and the scar over the knee-cap avoided if the incision be made at the outer side. To do this, a very small puncture may be made in front, and a probe introduced, the point of which may be made to project at the outer limit of the cavity. The probe may then be cut down upon, and a drainage-tube introduced, the anterior puncture being allowed to close. If the abscess be of considerable size, an incision must be made on each side, care, of course, being taken not to cut so deeply as to injure the capsule of the joint. If antiseptic precau-

are taken, it is necessary only to make an opening of sufficient size to admit a drainage-tube, but under other circumstances, the incision must be much more free. The burrowing beneath the fascia lata that not unfrequently follows abscess of the bursa patellæ, is due first to not opening early enough; secondly, to insufficient drainage; and, thirdly, to decomposition of the discharge, and cannot be regarded as an unavoidable accident of the case.

Disease of the Patella.—Sometimes, but very rarely, abscess of the bursa patellæ will give rise to disease of the patella itself. Caries of this bone secondary to suppuration of the bursa, is, so far as my experience goes, exceedingly rare. I have seen one case of the kind—that of a woman who was in the Hospital, under my care, several years ago. When admitted, she had several fistulous openings on the forepart of the knee-joint, through which the probe led down to a rough and carious patella. On inquiry it was ascertained that she had had inflammation of the bursa patellæ—"housemaid's knee"—which had run on to suppuration, but that the abscess had never been freely laid open. The present condition had resulted from that suppuration. The joint itself was unaffected; there was no pain in it, and its movements were perfectly free. I laid open the sinuses, and, finding the anterior surface of the patella soft and carious, removed with the gouge the diseased bone to which they led. About two or three weeks after this, the joint became suddenly swollen, evidently filled with pus, and the seat of acute pain. In consequence of the severity of the symptoms, it became necessary to remove the limb above the knee. After amputation, it was found that the disease had extended through the patellar cartilage, perforating it by a small aperture, and so given rise to suppuration within the joint.

Sloughing of the Bursa Patellæ occasionally occurs as the result of its inflammation and suppuration. A woman was admitted into the Hospital, in whom this bursa had inflamed and suppurated; and not only the bursa but also the integuments covering it had sloughed away, leaving in front of the knee a circular ulcer as large as the palm of the hand, having a flabby surface, and undermined, purple edges. The patella was not exposed. Under ordinary treatment, the ulcer slowly healed.

2. **Enlargements.**—We now proceed to the consideration of the second variety of disease of the bursa patellæ—that in which there are no evident signs of inflammation, but in which there is enlargement of the bursa, owing to the accumulation within it of bursal fluid, of this fluid mixed with solid bodies, or of solid fibroid deposits.

Simple Enlargement, or Dropsy of the Bursa.—The bursa may present a simple enlargement, dependent on the accumulation of fluid in its interior. Continued pressure exercised upon the bursa, as in kneeling, is the common cause of this affection, hence it frequently occurs amongst housemaids, and constitutes the true "housemaid's knee." But it is also common amongst other people, whose vocation necessitates long-continued kneeling. One case of the affection in University College Hospital was in a carpet layer; it was in all intents and purposes a "housemaid's knee." A man, aged thirty, who, in consequence of habitually kneeling upon the left knee in laying down carpets, had a tumor there as large as an orange, indolent, soft, and fluctuating, evidently an enlarged bursa, was admitted into the Hospital. It was tapped by means of a trocar, clear fluid was drawn off, and a seton was passed through the capula, and left in for six or seven days. Suppuration took place along the seton the tumor collapsed and contracted, and the patient left the Hospital, cured, on the twelfth day.

The *Treatment* of these tumors is very simple. If the effusion has taken place somewhat rapidly, and distinctly in connection with some injury, the

application of tincture of iodine, or a blister, will succeed in inducing absorption of the contained fluid. When the disease is more chronic, these usually fail. The fluid may then be withdrawn by means of the aspirator and pressure applied with an India-rubber bandage. If this does not succeed, a simple and successful mode of treatment consists in tapping the sac with a trocar and passing a seton through the cannula, either by means of a long straight needle, or by using an eyed probe, and cutting down upon the end of it with a scalpel. The seton-threads should be left in until they excite free suppuration and then be withdrawn. The only risk of this treatment is, that empyema may form than can readily drain away by the apertures through which the seton passes, and consequently a septic abscess of the bursa may result, requiring a free incision for its relief. In order to avoid this risk antiseptic drainage may be substituted for the seton. A small puncture is made, and an India-rubber drainage-tube inserted with all antiseptic precautions. In many cases a week or ten days' drainage will suffice to correct the tendency to oversecretion without any inflammation or suppuration being set up. The result is, however, made more certain by exciting a slight degree of simple inflammation by injecting the cavity at the time the tube is inserted with carbolic acid lotion (1 in 20), or solution of chloride of zinc (20 gr. to ℥j), or tincture of iodine.

Chronic Enlargement with Melon-seed Bodies.—The next affection to which the bursa patellæ is liable is closely allied to the last, and appears to be an advanced degree of it. It consists in a chronic enlargement of the bursa, the coats of which are more or less thickened. The contents of the bursa, so enlarged, consist of a dark fluid, in which float a number of smooth oval bodies, of the size and shape of melon-seeds. I have seen this condition in both the male and the female. It may be distinguished from simple enlargement of the bursa, by the peculiar crackling sensation which is communicated to the hand when the tumor is manipulated. This arises from the melon-seed bodies floating about and rubbing against each other.

The *Treatment* of this affection consists in making an incision, with antiseptic precautions, free enough to allow the melon-seed bodies to pass out. The cavity may then be syringed out two or three times with carbolic acid lotion, to insure the removal of all the solid bodies; a drainage-tube is then inserted and retained for a week or ten days, the wound being treated by some form of antiseptic dressing.

Solid Tumors may be formed in connection with the bursa patellæ. By many these are supposed to be the result of a deposition of a fibroid material, which gradually takes the place of the fluid of an ordinary "housemaid's knee," and which, instead of taking the form of melon-seed bodies, is deposited in concentric masses, and thus accumulated in the interior of the cyst. This has not been the case, however, in many instances that I have seen. In these cases I believe there is a true fibroid growth in the wall of the bursa from the very first; the tumor is never fluid, but hard and solid from the commencement, and continues slowly to augment in size, until it occasions sufficient inconvenience to require removal. In some cases there has been a previous syphilitic taint; the patient complains of pain in the tumor like that which is experienced in nodes, and it is by no means impossible that there may be a syphilitic origin for these tumors. However that may be, in the cases that have fallen under my observation, the tumors have never been fluid, nor have they originated in pressure, but appear to have been primary deposits of fibroid matter.

Treatment. There is nothing to be done with such tumors but to dissect them out. This may be required in one or in both knees. With the most ordinary care the joint runs no risk; but much trouble may arise from open-

ing up that layer of deep fascia which, after surrounding the knee, is fixed to the borders of the patella. Such an accident is liable to be followed by infiltration and deep abscess in the ham, unless careful attention be paid to drainage and to the prevention of decomposition in the discharges. In order to provide more efficient drainage, it will often be found convenient to remove the tumor by a curved incision at the outer border of the tumor instead of in the middle line. This plan has been repeatedly tried in University College Hospital with the best results.

DISEASES OF OTHER BURSAE.—The diseases of the Bursa Patellæ being taken as the type, the affections of the other more important bursæ require to be but briefly alluded to.

Enlargement of the Pre-hyoidean Bursa or of that between the genio-hyoid muscles is not very uncommon, forming a large, thin-walled fluctuating tumor in the front of the neck and beneath the chin. When the bursa between the genio-hyoid muscles is the seat of disease, the cyst may push up into the floor of the mouth between the genio-hyoglossi. When the pre-hyoidean bursa is affected the cyst tends to extend downwards over the larynx, forming one of the varieties of the so-called "hydrocele of the neck."

Treatment.—These cysts can usually be cured by tapping, with injection of chloride of zinc or tincture of iodine, followed by antiseptic drainage. The walls are too thin and their attachments too deep to make it advisable to attempt their removal by dissection.

The Bursa beneath the Deltoid is not uncommonly enlarged. The affection assumes most frequently the form of simple chronic enlargement with or without the presence of melon-seed bodies. It forms a rounded swelling, causing prominence of the deltoid with distinct fluctuation. The *Treatment* consists in aspiration and blistering. Should this fail, or should the soft crackling on movement show the presence of melon-seed bodies, an incision may be carefully made at the most convenient spot, and the sac emptied and drained for a week or ten days. This operation must not be undertaken without due consideration, and must be performed with the strictest antiseptic precautions, as the bursa frequently communicates with the articular cavity, and any septic process occurring in it would almost certainly lead to destruction of the shoulder-joint.

The Bursa over the Olecranon.—Inflammation in this bursa ending in suppuration is a common result of falls on the elbow, with or without a wound. It causes severe pain and redness, with œdema extending a long way above and below the joint. The pus may burrow some distance down the forearm unless early measures be taken to prevent it. The inflammation very rarely extends to the elbow-joint, but superficial necrosis of the olecranon sometimes occurs. Chronic enlargement with some thickening of the walls forms the affection known as "miner's elbow." Solid tumors of the bursa are rare. It is not uncommon to find the bursa the seat of gouty deposits. The *Treatment* of these affections is conducted on exactly the same principle as in the corresponding conditions at the knee.

The Bursæ about the Trochanter Major are occasionally the seat of chronic inflammatory enlargement or dropsy, and of acute inflammation terminating in suppuration. The latter condition is of great importance from its simulating hip-disease, or sometimes causing it by implication of the joint. The diagnosis can be made only by observing that the characteristic deformity of the hip is absent, and on opening the abscess the finger will not be able to detect either diseased bone or any connection with the joint. The treatment is conducted on ordinary principles.

The Bursa over the Tuberosity of the Ischium is sometimes enlarged, forming the condition termed "Weaver's bottom." The enlargement is often

solid, and may cause great discomfort in sitting. Under these circumstances it may be safely removed by the knife.

The **Bursa beneath the Psoas** is rarely enlarged, but cases have been recorded in which fluctuating tumors, containing serous fluid, have been met with in the groin, and have been supposed to have arisen in this way. These tumors are deeply seated, and closely resemble psoas abscesses; they become tense when the thigh is extended and lax during flexion. Their true nature can be ascertained only by the use of the aspirator. They must be treated on the principles already laid down, but the frequent communication of this bursa with the hip-joint must be borne in mind.

The **Bursæ in the Ham**, especially that beneath the inner head of the gastrocnemius, not unfrequently become enlarged. Their walls become slightly thickened, but nodule-bodies or solid enlargement are rare. The distended bursa forms a fluctuating swelling, which becomes tense during extension of the joint and lax during flexion. There may be some slight pulsation communicated from the popliteal artery, and the swelling may thus resemble an aneurism, but the pulsation is not expansile, and the tumor does not diminish in size on compressing the femoral artery. Sometimes by firm pressure the cyst may be made partially to empty itself into the knee, the signs of fluid in the joint then becoming apparent. These enlarged bursæ in the ham usually cause but little pain. The skin covering the swelling is normal in appearance. The *Treatment* must be conducted with caution, owing to the close proximity, if not actual communication, of the bursal tumor with the joint. Painting with tincture of iodine and blistering with elastic pressure may first be tried; if that fails aspiration followed by pressure may be tried; if that is not successful, injection with iodine may cure the disease. When everything else has failed, antiseptic drainage will usually effect a cure. In one case, after every other means had failed, Johnson Smith successfully dissected the cyst out, leaving the pedicle which passed under the gastrocnemius. The operation was performed under the carbolic spray, and the wound treated antiseptically.

The **Bursa beneath the Tendo Achillis** at the heel is sometimes diseased. It forms a fluctuating swelling on each side of the tendon, and may simulate disease of the ankle-joint. The treatment presents nothing peculiar.

Bunion.—When the bursa which lies towards the plantar surface of the head of the metatarsal bone of the great toe becomes enlarged, or when a new sac is formed upon the inner and posterior aspect of this bone, the disease termed a *bunion* occurs. In this affection, the enlargement of the bursa is usually secondary to an alteration in the shape and position of the great toe, which, in consequence of the pressure of narrow-pointed boots, has been thrown outwards in an oblique direction, so as to lie over or under some of the contiguous digits (Fig 602); in this way a sharp angle is formed at the junction between the first phalanx and the metatarsal bone of the great toe. This angle, being constantly pressed upon by the boot, becomes irritated; and for its protection, the bursa that is there naturally situated becomes enlarged, or an adventitious one forms. From time to time the bursa and the projecting angle become irritated and inflamed; and the morbid process thus set up may run on to suppuration of a very troublesome kind, a thin, unhealthy pus being formed, which is discharged through an opening that becomes fistulous, and may degenerate into a most troublesome indolent sore.

Treatment.—In the treatment of this affection, the first thing to be done is to relieve the pressure on the part by wearing properly shaped boots, made with the inner side of the sole straight from the toe to the heel. If accidental inflammation be excited in the part, it must be allayed by the use of warm foot baths, and fomentations; the cutaneous irritation that is left may best be

removed by painting the surface with a strong solution of nitrate of silver. The faulty direction of the toe may best be remedied by using the ingenious contrivance (Fig. 603), the action of which consists in drawing the everted end of the toe inwards by the constant action of a slender steel spring. Should these means fail, the position of the toe may be remedied by the division of the external lateral ligament of the metatarso-phalangeal articulation, or of the tendon of the adductor pollicis, or of the inner head of the *dexter brevis pollicis*; the toe, when restored to its position, being for a time kept fixed upon an under-splint.

Fig. 602.—Distorted Foot, from Pressure and Bunion.

Fig. 603.—Apparatus for Deformity of Foot as in Fig. 602.

As these methods of treatment are, however, seldom successful, it has been suggested by C. Hoar, late House Surgeon to University College Hospital, to perform antiseptic osteotomy of the metatarsal bone of the great toe through the neck of the bone. This operation has been most successfully performed by A. E. Barker in one case, and deserves a further trial. Barker removed a small wedge-shaped piece from the inner side of the metatarsal bone, and fracturing the remainder, brought the toe at once into good position.

Occasionally in elderly people the bunion will inflame and suppurate, and the mischief, extending to the metatarso-phalangeal articulation, will cause disorganization of the joint. This is a state of things not devoid of anxiety, as it not unfrequently happens that, if the constitutional powers be enfeebled by age, a low stoughy erysipelatous inflammation may be set up in the foot, which eventually may terminate fatally. Should the joint be irretrievably disorganized, and the patient's strength admit it, the toe should be removed by amputation—after which the carious head of the metatarsal bone will usually heal without difficulty.

DISEASES OF SHEATHS OF TENDONS.

The synovial sheath of a tendon is liable to two forms of disease; viz., the development of a small sac in immediate connection with it, forming a cystic tumor, and acute and chronic inflammation or *tenoosynovitis*. The tendons of the hand are most liable to both these affections.

Classification.—The term ganglion is applied to both these conditions, and thus leads to some confusion. The *simple ganglion* is a small cyst of new for-

mation in close connection with a synovial sheath; the *compound* is a dilatation of the sheath itself, and is a consequence of chronic tenosynovitis.

Simple Ganglion consists of a cyst varying in size from a cherry stone to a large marble, and containing sometimes a clear transparent fluid of a yellowish color, but more commonly a pinkish or yellowish gelatinous substance. It occurs as a smooth, globular, elastic, and tense tumor, usually situated on the back of the wrist, where it forms a distinct round projection; it may occur also on the dorsum of the foot. In both situations it is distinctly connected with the sheaths of the extensor tendons. As the ganglion increases in size, it often gives rise to painful sensations in the parts below it, by pressing upon the neighboring nerves, thus, a ganglion at the back of the wrist often produces pain and weakness in the hand, by compressing some of the branches of the radial or ulnar nerve which are stretched over it.

Ganglion is by far the most common of all the tumors that occur on the hand. In all cases of oval or rounded, smooth, elastic tumor on the hand or fingers, whether painless or neuralgic, the first point to determine is whether it be ganglion or not, but ganglion should always be suspected.

A small, hard, and painful ganglion, varying in size from a pin's head to a cherry-stone, is met with in connection with the flexor tendons of the fingers, usually on the proximal phalanx. If it interferes seriously with the use of the fingers, it may be dissected out.

The mode of origin of a simple ganglion is very doubtful. Paget looks upon it as a cystic transformation of the cells enclosed in the fringed processes of the synovial membrane lining the sheath of the tendon. Barth believes it commences as a pouch-like protrusion from the sheath, the neck of which becomes gradually narrowed till at last a separate cyst is formed lying on the sheath, but not communicating with it. There is no real evidence in support of either of these views.

Treatment.—When the ganglion is small, as on the back of the wrist, it may commonly be got rid of by being ruptured by forcible pressure with the thumb, or by a blow with the back of a book, or by being tightly compressed, by means of a coin wrapped up in a piece of lint, and firmly strapped upon the swelling. If it do not disappear in this way, the best plan is to puncture it subcutaneously by means of a valvular opening, to squeeze out its contents, scarify the interior of the cyst, and employ pressure. If the ganglion give rise to much pain and weakness, and cannot be made to disappear by the use of the means just indicated, it may usually be very conveniently and safely obliterated by passing a seton of two threads through it, dressing it antiseptically, and leaving it in for four or five days, until sufficient inflammation has been induced for the obliteration of the cyst. Should these means fail, it may be dissected out, if it be thought advisable to have recourse to this somewhat severe procedure, which is attended with some risk of inflammation extending up the sheath of the tendon. I have, however, on several occasions performed this operation, without any troublesome consequences ensuing.

INFLAMMATION OF THE SHEATHS OF TENDONS. TENOSYNOVITIS.—This is occasionally met with as the result of strains and twists of the hand, about the wrist, of the extensor tendons, or the long head of the biceps. It is very common in the extensor muscles of the thumb from leathering the *oar* in rowing. In this affection there is swelling of a puffy character, with tenderness when the part is pressed on or moved; and usually a peculiar *creack*ing sensation is communicated to the Surgeon's hand when he examines the affected part. The *creack*ing is especially marked in cases in which the

inflammation and effusion have become chronic, when the disease appears to partake of the nature of a diffused ganglion.

Treatment.—The treatment, when the disease is acute, consists in the application of gentle pressure by means of a bandage, with rest of the part; when it has assumed a chronic character, the application of blisters and the mercury and ammoniacum plaster will be found most useful.

Compound Ganglion is a chronic effusion into the sheath of a tendon without any manifest signs of inflammation, though it is usually regarded as a very chronic inflammatory process analogous to chronic synovitis of a joint. It is met with chiefly in the palm of the hand, and the dorsum, sole, or inner side of the foot. It may often attain a very considerable size, and then usually becomes irregular in shape, owing to several tendons being implicated by it. Often, in this form of ganglion, the sheath is thickened as well as dilated; and the contained fluid is clear and yellowish, though usually thinner than in the simple ganglion. The sheath itself is vascular, and lined by a red, fringed, and velvety membrane; the fluid may then be dark and bloody, and contain masses of buff-colored fibrin or a large number of granular bodies, like those met with in certain forms of enlarged bursæ. The appearance of a so-called compound ganglion at the wrist may in some cases be the first indication of disease of the bones of the carpus, as the synovial sheath comes in close contact with the bones. In a case lately in University College Hospital, the compound ganglion, which contained melon-seed bodies, was apparently cured by antiseptic drainage. Some months after caries of the carpus manifested itself, necessitating excision of the wrist-joint.

Treatment.—A ganglion situated in the palm of the hand, and extending under the annular ligament some little distance up the flexor tendons of the forearm, is a very troublesome disease. Syme recommended that the sac should be laid open, and the annular ligament divided. This seems to me an unnecessarily severe procedure; and I have in several instances cured the affection by milder means; in one, by injecting a small quantity of tincture of iodine into the cyst through a puncture in the palm, and in two or three other cases by the use of the seton. The seton is most easily introduced by squeezing the fluid from the palm into the sheaths of the flexor tendons above the wrist, making a puncture into these, and then pushing an eyed probe armed with two or three threads along the tendons under the annular ligament into the centre of the palm, where it is to be drawn out through a small incision made down upon it. The seton threads may be soaked in carbolic acid and lotion, and the operation and dressing conducted on antiseptic principles to avoid excessive suppuration, or an India rubber drainage tube may be substituted for the silk thread. Compound ganglia in other situations must be treated on similar principles.

DISEASES OF MUSCLES.

The voluntary muscles are not often the seat of primary disease of any kind. **Fatty Degeneration** of muscle, as met with in surgical practice, is usually the result of want of use. In such cases, the muscular fibres are merely atrophied, and the fat, which resembles normal adipose tissue, is accumulated between them. Such a condition is recovered from if the cause of the want of use be removed. True fatty degeneration, in which the protoplasm of the muscular fibres undergoes conversion into fat-granules, is not common in the voluntary muscles. **Ossification of Muscles**, that is to say, gradual atrophy of the muscular fibres with the development of the bone from the connective tissue between them, has been met with in very rare cases in the muscles of the back. **Inflammatory Affections** are usually

secondary, the muscle being implicated by extension from surrounding parts. Diffuse inflammation of the voluntary muscles with disseminated abscesses has been observed in pyæmia. Abscesses, as we have already seen in *pyæmia*, may enter the sheaths of muscles and cause considerable destruction of tissue. "*Rheumatic inflammation*" of muscles is met with as lambrage, intercostal rheumatism, etc., but of the exact nature of the process we know but little.

Syphilitic Disease of Muscles has been already described (vol. i. p. 1473). It occurs as diffuse sclerosis of the muscle or gummata. Gummata have been met with in the triceps, vastus externus, sterno-mastoid, and many other muscles, but especially in those of the tongue. They grow slowly infiltrate surrounding parts, and soften if not relieved by treatment. They are not unfrequently multiple. They are accompanied by aching pain, and stiffness of the affected muscle. They derive their importance chiefly from their resemblance to some of the tumors to be immediately described, which has occasionally led to their being cut out. The diagnosis is effected by the history of syphilis, the slow growth and hardness of the tumor, its subsequent softening, and the pain at night. They disappear or diminish rapidly under iodide of potassium.

Tumors of Muscle.—Primary tumors of muscle are not common. The growths met with are the various forms of sarcoma, sometimes containing much fibrous tissue (fibro-sarcoma), sometimes soft round-celled or spindle-celled sarcoma), chondromata, myxomata, fibromata, nevoid growths, and hydatid cysts. Primary carcinoma of muscle never occurs. Teevan collected with much industry the particulars of 62 cases of tumors of muscles of all kinds; about one-third of these were soft sarcomata, 16 were described as fibrous, 8 cystic, 5 hydatid, and 5 nevoid. Malignant sarcomata are most common, according to my experience, in the lower limb. When the upper

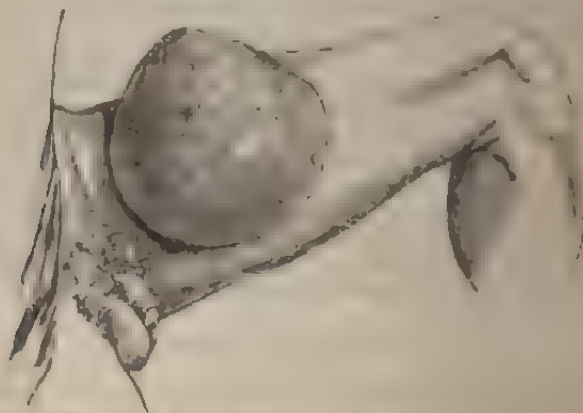

Fig. 604.—Fibro-sarcoma of the Sartorius Muscle.

limbs are affected, the muscles that have, according to Teevan, been most frequently attacked are the pectoralis major, deltoid, and biceps. The muscles of the trunk and neck are seldom diseased, with the exception of the rectus abdominis, which appears to be very liable to tumors.

Of twelve consecutive cases that I have had under my care in which tumors of different kinds developed primarily in muscular tissue, the following are the particulars. The first case was that of a woman about 40 years

of age, in whom a fibro-cystic tumor, as large as a cocoanut, developed in connection with the tensor vagine femoris, forming a large mass, which I dissected out readily from over the hip. The second case was that of a lad about 18, in whom a cystic tumor, as large as a fetal head, thick walled, and containing clear fluid, developed in the substance of the adductor brevis of the thigh, from which it was dissected out with no little difficulty, and with a fatal result. The third case was that of a man from whom the accompanying drawings are taken (Figs. 604, 605, 606), in whom a fibro-sarcoma

Fig. 605.—Back View of Tumor, showing Sartorius Muscle.

Fig. 606.—Front View of Tumor, laid open and showing Sartorius, a.

developed within the sheath of and in the substance of the sartorius muscle of the left thigh, in consequence of a strain. After growing slowly for about six years, it had attained the size of a child's head, when I removed it, together with seven or eight inches of the muscle from the inside of the sheath of which it had originated, and with which it was closely incorporated. The sheath of the femoral vessels which was exposed for a considerable extent, was unaffected by the disease. Recurrence took place in less than twelve months in the cicatrix, and when the secondary tumor had attained the size of an ostrich's egg, it was removed, the patient making a good recovery, but the disease again returned, and eventually proved fatal. The fourth case was that of a man aged about forty, in the sole of whose foot a cystic tumor, about as large as a goose's egg, was developed, springing from the flexor brevis digitorum. This was carefully dissected out; but in a few months the patient returned, with a solid, elastic, rapidly growing tumor, evidently a malignant sarcoma, developed in the cicatrix (Fig. 607). The foot was amputated, and on section the mass proved to be a soft sarcoma, and to have developed from the muscular structure just named (Fig. 608).

In three cases the tumors were hydatid. In one patient, a young woman, the disease was seated in the deltoid; in another, a medical man, about 50 years of age, the tumor was seated at the outer edge of the latissimus dorsi; and the third was a gentleman about 60 years old, in whose biceps the disease commenced. In each of these cases, excision of the tumor was successfully practised.

In the eighth case the tumor was an enchondroma in the tibialis anticus. I have seen two other cases of enchondroma in muscles: one situated in the vastus externus of the thigh; the other in connection with the pectoral muscle. The ninth case was a sarcoma of the rectus femoris in a man aged 21, which I excised, the tenth, a malignant growth in the anterior abdominal wall in an elderly gentleman, the eleventh, a soft sarcoma of the muscles of the calf in a middle-aged lady, for which amputation was practised; and the twelfth, a sarcoma of the forearm in a lad.

Tumors developing primarily in the intermuscular areolar planes are of very common occurrence; but these are very different from, and must not be confounded with, true tumors of muscle.

The *Treatment* of these various muscular tumors must be considered on ordinary surgical principles. When of an innocent character, as cystic or hydatid, fibrous, erectile, or enchondromatous, they may be dissected out from the muscular tissue amongst which they lie, and no fear of recurrence need be entertained.

When they are malignant, amputation of the limb, if the tumor be favorably situated for such an operation, is generally the only resource; partial

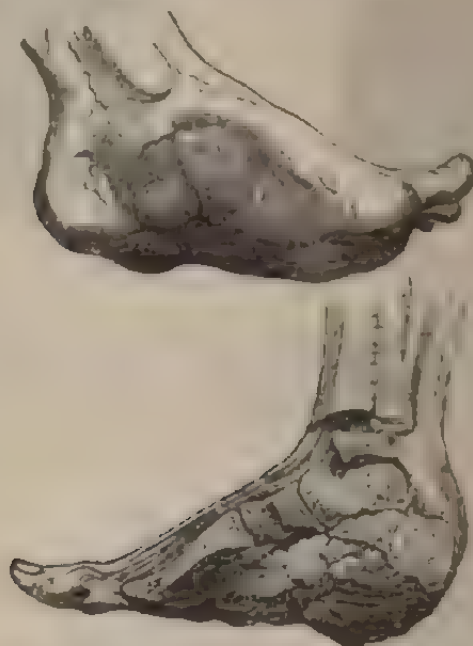

Fig. 607.—Malignant Tumor in Sole.

Fig. 608.—Section of Foot, showing situation of Tumor.

operations are usually worse than useless, as they are followed by a speedy recurrence. Treves has made the ingenious suggestion of applying to malignant tumors of muscle the same rule of practice that guides us in operations on bones similarly affected; viz., to remove the whole of the organ that is the seat of disease, excising the entire muscle from its origin to its insertion, and thus eliminating from the system the whole of the morbid mass, which will be confined within its sheath—a structure that for a long time resists the outward pressure of a morbid growth. The suggestion is founded on correct pathological principles; the only objection to it is its difficulty of application in actual practice—there being few muscles so situated that they could with safety be completely extirpated.

CHAPTER LIV.

DEFORMITIES.

LATERAL CURVATURE OF THE SPINE.

THIS affection, on account of the frequency of its occurrence, the deformity it occasions, the tediousness and uncertainty of its cure, has received a good deal of attention from various Surgeons; and much has been written on it by those who have specially devoted themselves to its treatment; yet the whole of its pathology and management lie in a very narrow compass.

Lateral curvature of the spine most commonly commences at an early period of life, usually between the ages of twelve and eighteen—seldom before the one, and not very commonly after the other. Girls are most frequently the subjects of this deformity, which but rarely occurs in boys. It appears to consist simply in a relaxation of the muscles and ligaments of the spine; in consequence of which the vertebral column, being no longer able to support the weight of the head, neck, and shoulders becomes curved to one side, a corresponding deviation taking place in the opposite direction at a lower portion of the spine, in order to preserve the equilibrium between the two sides of the body (Figs. 609, 610). The first curve usually takes place in the upper or middle dorsal region, the

Fig. 609.—Lateral Curvature and Rotation of Spine.

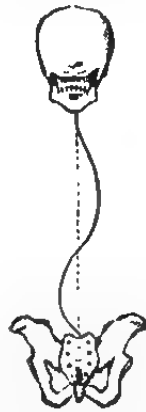

Fig. 610.—Outline of Double Lateral Curvature.

Fig. 611.—Quadruple Curve.

convexity tending towards the right side; the second or compensating curve occurs in the lumbar region, the convexity looking towards the left. In some instances there is a quadruple curve (Fig. 611). At the same time that these lateral curves take place, there is a tendency to rotation of the bones of the spine upon one another, in such a way that the bodies of the

vertebrae forming the dorsal curve are twisted slightly to the right, while those which enter into the formation of the lumbar curve are turned slightly to the left (Fig. 609). This twist is sometimes slight, but in other instances it is very marked, so that there is a double displacement—lateral and rotatory.

On examining the bones and intervertebral fibro-cartilages after death, even in cases of very considerable distortion, no disease will appear in them; except, perhaps, that the bodies of some may have been slightly compressed where they form the principal concavity of the arch. The ligaments appear to be stretched, relaxed, and somewhat weakened; and the muscles are usually pale, flabby, and apparently wanting in power.

MECHANISM.—From a consideration of the pathology of this affection, its mechanism becomes sufficiently apparent. The spinal column, being composed of a number of separate bones, possesses no firmness in itself, or power of self-support, but is maintained in the erect position by the close manner in which its separate elements are knit together by ligamentous and muscular structures, and by the way in which, when thus bound together as a whole, it is supported on each side by the strong mass of the erector spinae and its prolongations. The proper tension of these ligamentous supports and muscular masses is especially necessary for it to maintain the weight of the head and shoulders, which is thrown on the cervical and the upper portion of the dorsal spine. If, from any cause, the ligaments become relaxed, and the muscles lose their tone, or if the weight of the upper part of the body increase disproportionately to the augmentation in the strength of the ligaments and

muscles that support the spine, the vertebral column will necessarily give way under the pressure to which it is subjected in a direct line from above downwards, and will consequently become curved. Most commonly, indeed almost invariably, this takes place in a lateral direction, the spine yielding more readily in this than in any other. In some rare cases, however, the lower portion of the cervical or the upper dorsal region will project backwards in an arched manner, constituting the disease termed **Kyphosis** (Fig. 612); and in other cases, of still less frequent occurrence, there may be incurvation of the spine in the dorso-lumbar region, giving rise to **Lordosis** (Fig. 613).

The directions in which these various curves take place are exaggerations of the natural inclination of the spinal column. In *lateral curvature*, the chief convexity takes place towards the right side, causing a projection of that shoulder, which in most right-handed people is somewhat more prominent than the other. In *kyphosis*, the incurvation takes place in the lower cervical and upper dorsal regions, which are naturally prominent; and, in *lordosis*, the incurvation is most marked in the lumbar region, in which there is naturally a curve forwards.

CAUSES.—These various kinds of deformity, as has already been stated, usually commence in girls about the age of puberty; at a time of life when the tonicity of the muscular system not unfrequently becomes lessened by the occurrence of anemia and those states of impaired health that so frequently attend the establishment of the uterine function, and before the osseous and ligamentous structures of the body are fully developed. At this period of life, also, it frequently happens that the spine becomes rather

Fig. 612 —
Kyphosis.

Fig. 613 —
Lordosis.

suddenly elongated by a rapid increase in growth; or that it becomes over-weighted by the body developing, and the shoulders and bust becoming unduly stout and expanded. Indeed, so frequent is the occurrence of a certain degree of lateral curvature of the spine from these various causes, about the age of puberty in girls, that few escape a tendency to deviation; of so slight a kind, however, as not to admit of recognition as a disease. But if this tendency be increased by injurious habits, amongst which are all one-sided postures in which the body is twisted, as in playing certain games, some musical instruments, or in leaning over a table in drawing and writing, the slight deviation may rapidly increase until it assumes the true characters of lateral curvature. Girls who grow too rapidly are especially predisposed to lateral curvature. Their strength does not keep pace with their growth. The feet, ankles, or knees often give way, and the spine inclines to one side. But lateral curvature is common also in girls of a totally different make. Young women of a short and thick build, in whom the bust and shoulders become largely and early developed, are very liable to lateral curvature. In them too great a weight is thrown on the spine before its osseous and ligamentous structures are sufficiently developed and solidified to enable it to support this burden. I do not think that there is any evidence to show that this is either a strumous or a rickety affection; indeed, so far as my observation goes, I should certainly say that strumous girls are less liable to the disease than those of a nervous temperament; and it occurs at an age at which rickets is practically unknown. Amongst the more common predisposing causes must undoubtedly be reckoned the sedentary occupations and enervating habits commonly encouraged in girls in the wealthier ranks of life, which, by preventing due muscular development, at the same time that they induce a general loss of tone in the system, may directly occasion the disease. In growing lads, lateral curvature may be produced by a habitually maintained faulty position, as in sitting too long at the desk, or in following certain occupations. An inequality in the focal length of the vision of the two eyes is another very common predisposing cause of lateral curvature, the patient habitually twisting the body forward on the side of the defective eye, so as to endeavor to accommodate the vision of it to that of the stronger one. That the real cause of lateral curvature of the spine is to be found in faulty habits of life, and not in sex, is evidenced by the rarity of the affection amongst girls of the laboring class, as compared with its frequency amongst those of the wealthier orders of society.

The causes of the antero-posterior curves are usually to be found in some faulty habits of the patient; either giving rise to an habitual stoop, and thus laying the foundation for kyphosis, or throwing too great a weight on the loins, and thus giving rise to lordosis. Myopia and other impairments of vision causing the person so affected to stoop, in order to bring the page nearer the eye in reading, is a common cause of round shoulders, and in more extreme degrees of kyphosis.

SIGNS OF LATERAL CURVATURE.—The signs of this affection, when it is well marked, are distinctly obvious. The serpentine character of the curve, its double nature, the convexity on one side usually looking to the right shoulder, and on the other to the left loin, will render its nature evident. Most commonly it commences in a gradual manner, the first condition that attracts attention being the prominence of the right scapula, which is supposed to be "growing out;" or the sterno-clavicular articulation on the same side, or some of the cartilages of the ribs, have been observed to project. Whenever the Surgeon is consulted for such symptoms, he should at once examine the spine, which he will generally find to have an inclination to the right side. In the early stages of the disease, when the deviation is not very

distinctly marked, the readiest mode of determining it is to let the patient stand upright, taking care that the feet are well placed together, and that the attitude is not forced but natural; the Surgeon should then run his finger down the back from one spinous process to another, touching each as he passes it with a pen dipped in ink; in this way, when he has reached the lower part, he will have mapped out the course of the vertebral column, and thus may see at a glance the nature and extent of its displacement. At the same time, he will probably observe that the two hips do not exactly correspond, the left being somewhat thrown out. Very commonly there is a good deal of neuralgic tenderness about the spine, constituting the ordinary irritable or hysterical spine, and at this early stage there may be anemia and symptoms of impaired nutrition.

As the disease advances, the curvature becomes more marked, and at the same time, owing to torsion of the column, assumes a slightly angular character where most convex. The ribs on the right side are thrown out and bulging, and carry up the scapula with them, whilst those on the left are sunk and depressed (Fig. 614). In fact, the whole of the side of the chest and

Fig. 614.—Lateral Curvature of Spine.

body partakes in the projection of the spine on that side, and thus adds much to the general deformity; whilst the left side of the chest is correspondingly hollowed and sunk in. When the disease has advanced to this stage, general debility, emaciation, and pallor come on; the nutrition of the body being impaired, partly by the compression to which the thoracic and abdominal organs are subjected, and partly, doubtless, by irritation of the spinal cord induced by the curvature.

During the early part of the disease, the spine preserves its flexibility; and whilst the curve is still recent, and the patient young, if the weight of the head and shoulders be taken off, it will at once resume its straight direction. Thus, if the patient be lifted off the ground by raising her up with the hands under the axilla, or if she be laid down on her face on a flat couch, the back will fall into a straight position, or may readily be made to do so by slight traction. After the disease has existed for some time, or if the patient have passed that age at which consolidation of the bones and ligaments is completed, the distortion will continue per-

manently, in whatever position she may be placed. This is not only owing to the deformity of the spine, but to the ribs, and ligamentous and muscular structures generally of the trunk, having become distorted, shortened, and fixed in their abnormal position.

TREATMENT.—The treatment of lateral curvature of the spine should be conducted on rational principles; and, when divested of the mystery with which some interested specialists have surrounded it, it becomes no simpler as that of any other chronic surgical affection of the bones, joints, or muscles. There are three principles of treatment that require to be carried out in the management of these cases. The first is the improvement of the general health—unless this be effected, nothing can be done; the second is, to

strengthen the muscles of the spine; and the third, to take away as much as possible the weight of the head, neck, and upper extremities.

The administration of some of the milder preparations of iron, with a course of aloëtics for the regulation of the uterine function, is of great moment; at the same time, a nourishing diet of animal food should be allowed, and the patient encouraged to take exercise in the open air. By these means the nutrition of the system will be improved, and the tone of the muscles restored. The muscular power may be more directly strengthened by having the back well sponged with salt or vinegar in cold water every morning, and methodically rubbed from top to bottom. The friction should be applied principally to the erector spinæ muscles and their prolongations on each side of the vertebral column, and may be done either with the naked hand, or with some slightly stimulating embrocation. At the same time, if the patient's strength will permit it, but not otherwise, the use of the hand-swing may be allowed, or calisthenic exercises practised, and swimming learnt; by it the back is straightened, and its muscles braced more effectually than in any other exercise; these exercises, however, should not be continued if they induce a feeling of fatigue or exhaustion. Whilst this plan is being persevered in, the patient should be made to lie recumbent for a few hours daily, sitting or standing as little as possible. By these means, assiduously continued for some length of time, the muscles of the back may be strengthened, and increase of the deformity prevented; and in this way the slighter cases of lateral curvature, those in which there is a tendency to rather than a full development of the disease, may be cured. Should the focal length of the two eyes vary materially, this must be corrected by the use of proper glasses. All faulty habits must be corrected—one-handed games laid aside—in writing or drawing a sloping desk should be used, to which the child should sit squarely. If the girl rides, she should learn to ride alternately on the off and near sides.

In slight cases of lateral curvature, great evil may be occasioned and the deformity increased by the unnecessary employment of cumbersome machinery. The heavy apparatus that is often applied to growing girls overpowers and compresses, rather than supports and directs the imperfectly developed and still yielding skeleton. By the use of complicated machines the muscles of the back become weakened and atrophied from disuse; the pelvis is compressed and contracted; and those very evils are produced by the mechanician which it is the object of the Surgeon to avert or correct.

When the affection is further advanced, though the spine still continue flexible, if there be decided projection of the ribs on one side, and the shoulder and hip be prominent, with apparent difference in the length of the limbs, and much impairment of the general health, more decided measures of treatment must be had recourse to. In these cases, as in those just described, the constitutional powers must be carefully attended to on ordinary medical principles; iron, and good living, with fresh air, being the basis of the treatment. At the same time that we endeavor to improve the strength of the system in this way, and that of the muscles of the back, especially by cold bathing and frictions, it is essential to adopt means to take off the weight of the head and shoulders, and to prevent its continuing to keep up and to increase the deformity. This may be done in two ways: by keeping the patient in the recumbent position, or by allowing her to go about, wearing proper supports.

The recumbent position in the treatment of lateral curvature of the spine, though a valuable means as an adjunct to other measures, has been greatly abused, by being employed as an exclusive plan. This should not be, except when the patient is unable to stand or walk with comfort, as happens in

extreme cases, when it may be necessary to confine her for a time to this position, until the proper muscular power has been restored by the systematic use of electricity or other means. These instances, however, are very rare; too much so to constitute the rule in the treatment. Whenever the recumbent position is employed, the prone seems to me far preferable to the supine, for reasons mentioned when speaking of angular curvature of the spine (p. 431); and the best couch for the purpose is certainly Verrill's. The patient should be kept on this during the intervals of exercise, not being allowed to sit even at meals or to stand; she will very soon become accustomed to a position that at first appears constrained, and will, probably, speedily be able to sleep in it.

The **Mechanical Contrivances** constructed for the purpose of taking the weight of the head, neck, and upper extremities off from the weakened spine, are of very various forms, and have had much ingenuity expended in their construction. They all have three principal objects, however much their details may vary, viz.: 1, to form a broad basis of support round the pelvis, by means of a strong well-fitting band; 2, to carry off the weight of the head and upper extremities from the spine by means of lateral crutches, which transmit it to this band; and, 3, to influence the convexities of the spinal curve by means of movable plates, acted upon by rack-and-pinion or screw power. The best of these mechanical contrivances for supporting the weight of the head and shoulders, is the apparatus represented in the accompanying woodcut (Fig. 615). By it the projection of the right shoulder may be

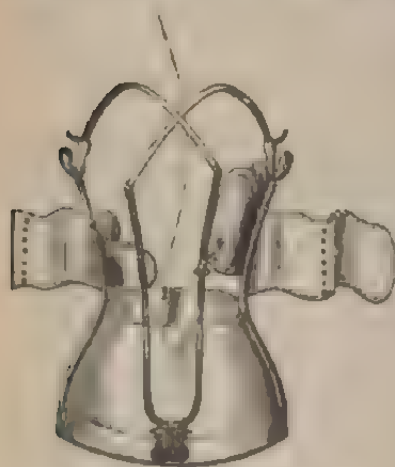

Fig. 615.—Spinal Support for Lateral Curvature.

gradually brought down, the left one raised, and the weight of the whole of the upper part of the body supported. By this contrivance alone, properly and carefully adjusted to the condition of the deformity, most patients may be treated without the necessity of any confinement whatever: the spine being by degrees restored to its proper direction by very gradually increasing the pressure and support of the instrument, at the same time that the general health is carefully attended to, and the patient has the benefit of good air. At first the instrument need be worn only during the day, but after a time it should be kept on at night as well. In long-standing and severe cases of lateral curvature of the spine, when its flexibility is lost, and the projection of the ribs has become permanent, a cure cannot be expected, nor can it

be brought about by any means; but the patient will derive great comfort and support from the use of this excellent instrument, and the increase of the disease may thus be prevented. Sayre's plaster jacket has been used for lateral curvature, but is now generally condemned, as it prevents movement completely, and thus increases the weakness of the muscles.

The treatment of *Posterior Excurvation* of the spine, without caries or other organic disease of the vertebral column, is best conducted by the use of the instrument here figured (Fig. 616), which is constructed essentially on the same principles as that for lateral curvature, with the exception that the

back-plate is so arranged as to press upon the projection, and thus gradually to bring it into proper position. In cases of kyphosis especially, attention should be directed to the sense of vision, and myopia or other impairments should be corrected by the use of glasses, the stoop being often dependent on near-sight.

In *Posterior Incurvation* the apparatus here figured (Fig. 617) will be found the most useful appliance. In fact, all these varieties of spinal curvature

Fig. 616.—Spinal Support for Posterior Excurvation.

Fig. 617.—Spinal Support for Posterior Incurvation.

may be remedied by the use of instruments constructed and acting on the most simple mechanical principles.

DEFORMITIES OF THE NECK AND LIMBS.

Various deformities, such as *squint*, *wry-neck*, and *club-foot*, are due to a disturbance of the normal equilibrium that exists between antagonistic muscles so that, by the paralysis of one set, or by the spasmodic action of the other, the proper balance of power is lost, and the limb or part deviates from the position that is natural to it, being drawn aside by the more powerful set of muscles. These deformities may be congenital, or they may be acquired.

The primary mischief is, in many cases, seated in the nervous system; in others, but more rarely, in the muscular. The ligaments and bones become only secondarily altered in shape, being shortened or compressed on the side towards which the limb or part inclines or is drawn. Fasciæ also become shortened and tense, and the disused muscles are apt to become soft, wasted, and flabby. The contracted muscle after a time becomes permanently rigid and shortened.

CAUSES.—The causes of these deformities are very various; but they may be referred to the following heads.

1. **Prolonged Abnormal Position** of a limb, as in an unreduced dislocation or an ankylosed limb, may lead to permanent deformity. It may be taken as a general pathological law that ligaments, fasciæ, and to a less extent muscles, if kept for a sufficient length of time in a continuously relaxed state, become shortened to accommodate themselves to the position in which they have been placed, and thus render the displacement, which originally caused the relaxation permanent. The most marked example of this is seen

in cases of psoas abscess, in which the patient has been confined to bed for months before death with the knees constantly flexed. After a time complete extension becomes impossible, and dissection proves that this is due to shortening of those ligaments that are relaxed in flexion. A similar shortening of ligaments or fasciæ may occur after fractures, if the parts be kept for too long a time in one position, more particularly if they be bound and matted together by the pressure of tight bandages. There is no danger however of such a condition being developed in the time ordinarily required for the treatment of a fracture. Some forms of congenital club foot have been supposed to be due to a prolonged abnormal position of the limb during intrauterine life, but the evidence of this is not very satisfactory.

2. **Contraction of inflammatory new growths or of tissues which have been infiltrated with inflammatory exudations**, is a fruitful cause of deformities. As examples, may be mentioned, the contraction of the cicatrices of burns in any part of the body, acquired talipes equinus from contraction following a deep-seated abscess in the calf, and contracted knee or hip after inflammation of the joint.

3. **Derangement of the proper antagonistic action of certain groups of Muscles.**—This may arise from a variety of causes.

(A.) *The Position of the Limb* may give one group of muscles an advantage over their opponents; thus in disease of the knee, the flexed position gives the flexor muscles an advantage over the extensors, and we consequently find that the head of the tibia becomes after a time displaced to a greater or less degree backwards into the ham, merely by the tonic contraction of the muscles without any weakness or paralysis of their opponents.

(B.) *Paralysis or paresis of one group of muscles*, the contractility of their antagonists continuing normal, is a common cause of deformity, as the relative balance of action is destroyed, and the stronger muscles will pull the part over to their side. The causes of this condition may be in the muscles themselves, in the nerve supplying them, or in the central portions of the nervous system.

The muscle itself is seldom the seat of the primary lesion. G. V. Porey has pointed out that a single muscle or group of muscles may be weakened, and their contractility in response to electricity impaired by excessive use without sufficient intervals of rest. This is often accompanied by spasm of the opponent muscles, sometimes tonic, but more often clonic, and thus deformity may result. This is not, however, a common cause of actual deformity.

The conductivity of a motor nerve is frequently abolished by wound, injury, pressure of tumor, exposure to cold, or neuritis from other causes. A good example of the effects of lesion of a motor nerve in producing deformity may be seen in the peculiar condition of the hand and forearm, described at p. 565, vol. I., as resulting from paralysis of the musculospiral nerve in certain fractures of the humerus. In paralysis of the facial nerve from cold the face is distorted by being drawn to the sound side. Internal squint may result from paralysis of the sixth nerve from pressure upon it as it enters the orbit, the external rectus losing its power and the eye being drawn inwards by the action of its antagonist, the internal rectus.

Disease of the central nervous system, more especially of the spinal cord, is a frequent cause of deformity, which is very common in infancy and early childhood, as a consequence of Infantile Paralysis. This disease is now known to be due to inflammation of the anterior gray cornua of the cord. At first there is extensive paralysis, which gradually clears up as the acute stage passes off, often leaving merely a single group of muscles permanently paralyzed, as, for instance, the tibialis anticus, and the extensors of the toes. As the result of this the foot becomes extended by the unopposed muscles

of the calf, and one form of acquired club-foot is produced. Little has made the important observation that many cases of deformity in infants appear to be due to mischief inflicted on the base of the brain during protracted and instrumental labors.

Another example of deformity from disease of the central nervous system is the club-foot and occasionally club-hand also, met with in cases of encephalocele or spina bifida.

c) *Spasm of a muscle or group of muscles* also may give rise to deformity, the opponent muscles remaining perfect in their contractility, but being over-balanced by the continued contraction of their antagonists.

Spasm may be the result of direct irritation of the central nervous system. This would appear to be the case in some forms of squint. It may also be reflex, resulting from some peripheral irritation. This we commonly see happen in cases of contraction occurring from the cutting of teeth, the irritation of worms in the intestinal canal, in the so-called hysterical contractions from uterine irritation, etc. From all these various causes, contraction and consequent deformity may arise. In some cases deformity will cease after removal of the cause; but in other instances, in which it has been of long duration, the deformity will continue, owing to the muscles having fallen into a kind of rigid atrophy, being shortened and wasted.

4. When deformity has arisen in the lower extremity as a consequence of any of the above conditions, it becomes greatly aggravated by the *weight of the body* acting on the deformed limb. This we see especially marked in old club-feet.

TREATMENT.—The *General Treatment* of deformity consists in removing the cause of the contraction in those cases in which it is dependent on central or peripheral disease or irritation that admits of remedy. Thus, if squinting arise from pressure upon the brain, the eye will assume its straight direction when the congested vessels are relieved, or the effused fluid absorbed; or if a contraction of the hamstring muscles arises from the irritation of worms in the intestinal canal, a purgative dose may cure the affection.

Electricity is perhaps the most valuable agent we possess for the treatment of those deformities that arise from paralysis of one set of muscles allowing those that retain their healthy contractility to draw the parts over to their side. Thus, for instance, if the muscles supplied by the external popliteal nerve, the *tibialis anticus*, the extensors of the toes, and the *peronei*—are paralyzed, so that the muscles of the calf, the *tibialis posticus*, and the flexors of the toes draw the foot into the position of *Talipes Equinus* and *Varus*, the electricity must be applied to the former group of muscles. The continuous current will be found the most efficient, faradization being of but little use if degenerative changes have commenced in the paralyzed muscles. In the case just described the sponge connected with the positive pole should be tied over the external popliteal nerve behind the head of the fibula, and the negative sponge applied freely over the paralyzed muscles till the skin becomes slightly reddened.¹

Friction properly applied forms a useful adjunct to electricity, and great care must be taken to keep the limb warm by proper clothing, without which the other treatment will be of little avail.

In many cases, the contraction may be slowly but very effectually overcome by the use of suitable apparatus, having a constant elastic or tensile action kept up by means of bands of vulcanized India-rubber or steel

¹ For details of the treatment of paralyzed muscles by electricity, I must refer the reader to special works on the subject, especially to *Electricity in Medicine and Surgery*, by G. V. Moore, and the selection from the Works of Duchenne (of Boulogne), published by the New Sydenham Society in 1884.

springs. The details of these various appliances, though belonging to the department of the instrument-maker, cannot be too carefully studied by the Surgeon, who, after all, in order to guide and control their action, must be thoroughly conversant with the mechanical principles involved in their construction. In many of the slighter and less chronic cases, the deformity may be remedied by the employment of these milder means, singly or conjointly; but in those which are congenital or more permanent, the *Division of the Tendons* at fault is the only mode of restoring the natural contour of the part. The orthopaedic department of surgery owes, in a great measure, its existence to the labors of Despech and Stromeyer, and its perfection to those of Little, Tamplin, and Adams.

Tenotomy.—By tenotomy, as at present practised, is meant the subcutaneous division of a contracted tendon by means of a narrow-bladed knife (Figs. 618, 619, 620) introduced obliquely through a puncture in the skin. In doing this, it should be borne in mind that the normal anatomical relations of parts are often a good deal disturbed in cases of deformity, so that tendons may be approximated to arteries and nerves from which, in the healthy condition of the limb, they are widely separated.

In the operation of tenotomy the knife may be used in one of two ways. In the majority of cases the tendon may be most conveniently divided by introducing the blade beneath it sideways, and then turning the edge against it, and scratching through it by a kind of fine sawing movement the handle of the knife being used as a lever, to press the edge against the tendon, whilst it is made tense by an assistant. The second way is to pass the tenotome superficially to the tendon between it and the skin, and then to turn the edge against it whilst it is made tight by an assistant. In this plan the

danger of wounding the skin is avoided. A drop or two only of blood is lost in the operation, and, as the divided tendon retracts with a kind of spasm, a gap will be left between the two ends, from half an inch to an inch in width, according to the previous amount of tension in the part. If the muscles have been contracted for some years it will commonly be found that the fasciae in the neighborhood of the tendon have become rigid and unyielding, forming cords or bands stretching across from the side of the gap. If these be very tense, they may be divided in the same way, but in many instances it will be found after the lapse of a short time, that they will yield by stretching, and consequently will not require division. After the section has been made, the small puncture should be closed with a pad of lint and a strip of plaster, the admission of air into the wound being carefully guarded against. The whole success of the operation depends on this. Should air enter spreading inflammation and suppuration will to a certainty be set up; whereas, if this be avoided the wound will heal without any inflammation beyond that caused directly by the injury. It is the entry

Fig. 618, 619, 620

Tenotomes.

of air, and not the substantial wound, that gives rise to spreading inflammation. Antiseptics are wholly unnecessary in tenotomy. If the substantial section be done with the most ordinary care, no danger of suppuration will result. After tenotomy the part should then be simply bandaged and either left without any apparatus, or supported by a splint in the case

position that it occupied before the tendon was cut, no attempt at extension being made for three or four days. At the expiration of this time repair will have commenced, and then proper mechanical contrivances may be adjusted for gradually restoring the normal position of the limb or part.

Savresadopts a different method. He makes extension immediately after the division of tendons, and fasciæ, and I have seen excellent results follow this practice. It is not, however, applicable in all cases, as, in some instances of talipes of old standing, the contraction appears to exist in the ligaments as well as in the more superficial structures. In such cases considerable resistance will be offered, and long-continued extension be required.

The mode of **Repair in Divided Tendons** has given rise to some controversy, there being two theories with regard to the process. According to one, the granulation-tissue between the divided and retracted ends gradually undergoes a process of contraction, analogous to what takes place in the cicatrix of a burn, so as to cause approximation of the cut ends of the tendon at the expense of the muscle, which becomes partially lengthened, until at last a transverse linear cicatrix merely is left at the line of section. Adams has, however, conclusively shown that this theory is erroneous, and that repair is effected by the formation of vascular granulation-tissue between the cut ends, chiefly from the sheath and soft parts around; that this undergoes gradual development into fibrous tissue; and that the tendon is actually lengthened and remains permanently so, by the formation of this new material, which eventually resembles the normal structure of tendon so closely that the microscope fails to detect any appreciable difference, and that it can be distinguished only by its more translucent appearance from the old tendon. In fact, the gap is completely filled up.

In cases of congenital malformation, the question frequently arises as to whether tenotomy should be performed in early infancy, or delayed to a more advanced age. As a general rule I think that, if operation will certainly be necessary, it should not be delayed; it is not more difficult at an early period of life than at any other, no danger attends it, and when performed during infancy, there is a far less chance of the deformity being permanent, than if the operation be delayed for some years. But it must be remembered that many slight deformities and contractions in infants may be removed without operation, by attention to proper mechanical and hygienic means. The Surgeon should not, therefore, be too ready to operate in slight cases at tender ages.

DEFORMITIES AFFECTING THE FACE AND NECK.

WRY-NECK.—Wry-neck, **Torticollis** or **Caput Obstipum**, arises from spasm of one of the sterno-mastoid muscles; the head being drawn to the affected side. On close examination in wry-neck, it will be found that there is a triple displacement of the head, which is drawn downwards, rotated from the affected side, and inclined laterally towards it. The features lose their symmetry. The half of the face, and even of the head, on the affected side, becomes less perfectly developed; and the true lines of the eyebrows, eyes, and mouth become displaced and lowered.

In torticollis, the affected sterno-cleido-mastoid will be found hard, defined, and shortened; sometimes both divisions of the muscles are equally tense, standing out in strong relief, so as to look almost like two distinct muscles. In other cases, one division, and then most usually the sternal, is chiefly affected. After a time the cervical vertebrae participate in and maintain the displacement, becoming rotated on their axes and curved. Eventually the whole spinal column shares in the displacement, and lateral curvature sets in.

The deeper muscles also become shortened, and the anterior margin and clavicular attachment of the trapezius will often be found tense and poorly naturally defined.

Causes.—Wry-neck appears to be occasionally congenital; more frequently it is acquired, coming on in childhood after measles or scarlatina, usually as a consequence of inflamed cervical glands, and is then due to the position instinctively assumed by the head in order to relax muscular tension on the inflamed side of the neck. It not unfrequently commences with an ordinary stiff neck from cold. In other cases, again, it is purely spasmodic, the tension of the muscle varying at different times, disappearing when the child is anesthetized, and being overcome by gentle traction. In these cases the spinal accessory nerve is probably at fault, and it is owing to irritation of it that the sterno-mastoid and trapezius muscles take on a spasmodic action. In spasm of both sterno-mastoids the head is thrown forwards, the muscles projecting in great relief. In these cases, the disease will usually be found to have had a rheumatic origin. Deformity in this situation may occur also from diseased cervical vertebrae, or from the traction of the centrix of a tumor. The conditions here, however, are peculiar, depending upon causes that are irrespective of the state of the muscles, which are not tense, and may thus readily be distinguished from the true form of the disease produced by the causes above mentioned.

Treatment.—The treatment of torticollis arising from permanent shortening of one of the sterno-mastoids, which is the common form of the affection, may best be conducted by dividing the inferior attachment of the muscle, and then allowing the head to regain its proper position. The division of the muscle is a somewhat delicate operation, on account of the important structures that lie immediately behind it. By making the incision, however, through it, from behind forwards, close to the sternum and along the clavicle, there can, if ordinary care be employed, be little risk of doing any damage, as these bones carry the lower attachment of the muscle forwards, and separate it from subjacent parts. The tension also, into which it is thrown by its spasm, draws it away from the carotid sheath. In several instances in which I have had occasion to perform this operation, no difficulty whatever has been experienced in dividing the sternal attachment of the muscle, which is usually very tense and prominent, by making a puncture on the inner side of the tendon, pushing a narrow director behind the muscle, drawing the latter forwards, and then passing an ordinary tenotome behind the tendon, with its flat side towards it, just in front of the upper margin of the sternum, and cutting forwards, whilst the muscle is put well upon the stretch. In dividing the clavicular insertion, the safest plan, I think, consists in making a puncture with a scalpel upon and down to the clavicle in the cellular space which lies between the two attachments of the muscle, and then pushing a long blunt pointed, narrow bladed tenotome beneath the insertion of the muscle, dividing this in a direction forwards. In this situation also the director may be used, unless the parts are very tense. Care must be taken of the external jugular vein at the outer edge of the muscle. Should this vessel run inconveniently close to the edge, the safer plan is to begin the operation from the outer side, making the first puncture here. After division of the tendon the deep fascia of the neck will sometimes be found stretching across in firm and tense bands; these, however, had better not be interfered with, as they will yield in time, and much risk of injuring the subclavian and carotid vessels would attend any attempt at their division. Nor should the edge of the knife ever be turned inwards. Care must be taken to divide the muscle completely, but not to carry the incision too freely or deeply. I have heard of

more than one case in which, from want of due precaution, abundant hemorrhage occurred, and of three in which fatal results followed the operation.

After the operation, the position of the head must be gradually rectified by proper apparatus. The best instrument for this purpose is the one invented by Bigg, and here figured (Fig. 621). It consists of a pelvic band, a vertebral stem, and arm-pieces, the object of which is to secure a firm basis of support to the neck-lever (1), and the maxillary lever (2). The neck-lever passes round the head, and takes its bearing against the temporal bone on the side towards which the head is deflected. The maxillary lever acts against the lower jaw on the opposite side—that which is turned up. By means of a ratchet-joint, the neck-lever, the action of which is vertical, turns the head from the side to which it is deflected, whilst the maxillary lever, acting horizontally, rotates the head on its axis. By the combined action of these two forces the head is restored to its vertical position, and the chin replaced in the mesial line. In this way the curvature of the cervical vertebrae may gradually be corrected; should it, however, have existed for a considerable time, it may have assumed a permanent character, and a twist in the neck will continue for life. If the operation be not delayed until too late in life, the features will gradually regain their symmetry.

The exposure and division of the spinal accessory nerve has been practised, but not, I believe, with any benefit. When wry-neck is secondary to disease of the cervical vertebrae, little can be done beyond maintaining the spinal column in as steady and fixed a position as possible, by means of mechanical support (vide Fig. 331, vol. i.).

In those cases in which the wry-neck appears to be dependent rather on paralysis of one sterno-mastoid, than on spasm of the other, electricity, and the application of strychnine to a blistered surface over the muscle, will be found most useful.

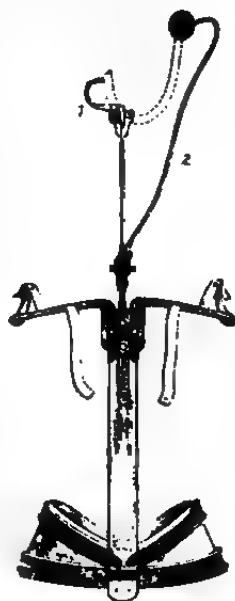

Fig. 621.—Bigg's Apparatus for Wry-neck.

DEFORMITIES OF THE ARM AND HAND.

Contraction of the Arm is not of very common occurrence, except as the result of burns. I have, however, met with four distinct forms of contraction of the forearm.

1. There may be ankylosis of the elbow-joint, the forearm being bent at a right angle with the arm, the result of disease of or around the articulation. If the ankylosis be fibrous, and the muscles strong and firm, a very useful limb may be restored by breaking down adhesions, under chloroform, by forcible flexion and extension, and then using passive motion, friction, and douches. Should the muscles be very flaccid and wasted, forcible extension may leave a permanently weakened limb, over which the patient has lost the power of flexion. In such cases, I have found gradual extension, made by means of an angular splint, acted upon by a ratchet-apparatus, the safest means of restoring the utility of the arm. If the ankylosis be osseous, the bone should be resected, a wedge-shaped piece being sawn out, and a false joint allowed to form.

2. The biceps may, by its contraction, occasion a permanent flexion of the arm. This contraction of the biceps may be hysterical or rheumatic. When hysterical, occurring in young women, it requires the ordinary constitutional treatment of hysteria; should this fail in removing it, extension may be made, under chloroform, and the arm kept in the straight position for a time. When it is rheumatic, or of organic character, and permanent, section of the tendon and its aponeurosis may be practised, due care being taken of the artery and nerve. This operation is most safely done by introducing the tenotome to the inner side of the tendon, slipping it under, and cutting upwards and outwards; the artery being guarded and pushed to the inner side by the pressure of the left forefinger.

3. The forearm may be forcibly pronated and flexed, as the result of chronic inflammation of the radio-humeral articulation. Here, forcible supination and extension, under chloroform, is the best remedy.

4. The forearm may be bent on the arm, in consequence of the contraction of the cicatrix of a burn along the inside of the limb. In this case, the plastic operation described at page 487, vol. i., must be practised.

Ankylosis of the Arm in the Straight Position is a condition of very serious inconvenience, the limb being almost useless for all ordinary purposes

Fig. 622.—Contraction of Supinators of Forearm and Extensors of the Hand.

of life. In cases of this kind, the treatment to be adopted must depend upon whether the ankylosis be fibrous or osseous. If it be fibrous, however firm, the forearm may always readily be brought into a rectangular position by flexion under chloroform, and the mobility of the joint may then be improved or restored by passive motion, traction, and douches. If it be osseous, a wedge of bone must be removed, and the case treated as an

Fig. 623.—Contraction of Flexors and Pronators of the Hand.

ordinary instance of excision of the elbow, with a view of establishing a false joint.

Acquired Contraction of the Muscles of the Forearm implicating the Hand is occasionally met with in adults. I have seen it in two opposite conditions; that of forcible extension Fig. 622, and that of forcible flexion and pronation Fig. 623. In both instances it appeared to have been the

result of excessive use of certain muscles; in the first case in wringing out clothes, in the other in cutting with very heavy shears. In the case of flexion and pronation, it was interesting to observe that, when the fingers were extended, the wrist became flexed, and when the wrist was extended the fingers became bent in. In these cases change of occupation, friction and galvanism, with the use of a straight splint, were advantageously resorted to, a cure being eventually effected.

Paralysis of the Extensors and Supinators, owing to injury of the musculospiral nerve consequent on fracture of the humerus, with or without tonic contraction of the flexors and pronators, has been described at page 565, vol. i.

Club-hand.—A deformity resembling club-foot is occasionally, though rarely, met with in the hand. The contraction may occur in two directions; either in the sense of preternatural flexion, or in that of abnormal extension of the member. It has been described by Cruveilhier, Voillermier, and Smith, of Dublin. In most of the cases that have been met with, there was a certain amount of deformity of the lower end of the radius, with congenital dislocation of the wrist; and in Smith's case there was an accessory semilunar bone in the carpus. Little, if anything, can be done by surgery for the relief of this deformity; though some benefit might possibly result from the division of any tendons that were preternaturally tense.

Arthritis Deformans or Rheumatoid Arthritis of the hand is a common affection. In this condition, the fingers which are thickened and stiffened are partially bent towards the palm, and at the same time turned towards the ulnar side. The articulations are swollen, and in the earlier stages painful. The disease rarely occurs before middle age. It is more common in elderly people, and especially those of the laboring class, whose hands have been much exposed to the weather, with the fingers bent as in holding reins or agricultural implements. The deformity is permanent and incurable.

Contraction of the Fingers.—One or more fingers may be bent in consequence of injury of the flexor tendons; the skin and fascial structures of the palm remaining sound with the exception of some cicatricial tissue. Such a contraction is incurable, as a portion of the tendon has probably sloughed away. In the true digital contraction, commonly called *Dupuytren's contraction*, its pathology having been pointed out by that great Surgeon in 1832, the tendons and their sheaths are unaffected, the deformity being due to changes taking place in the fascial structures outside them. Most commonly this commences in the little finger, and thence gradually extends to the ring and middle fingers, which become so forcibly and firmly curved inwards, that their extension is not practicable. This deformity results usually from frequent and continued pressure on the palm of the hand, as in leaning on a round-ended stick in walking, or in those trades in which an instrument is pressed into the hollow of the hand. It occurs, however, in persons in the prime of life without any apparent exciting cause. In such cases I have always found it associated with a rheumatic or gouty diathesis. On examining the contracted fingers, projecting ridges will be felt extending from the palm to their anterior aspects; and on endeavoring to straighten them, these ridges will be found to become stretched, and the palmar fascia to be rendered tense. The skin covering these fascial ridges is at first free, but after a time becomes adherent to them. So firmly are the fingers contracted, that by no effort can they be extended.

Pathology.—To Dupuytren we owe our knowledge of the true pathology of finger contractions. He found on dissecting a hand which was the seat of the disease, that after the removal of the skin, which was loose and flaccid, the contraction continued as before, and this, therefore, could not be its seat:

that the palmar fascia which was exposed, was tense and shortened, while from the lower aspect some cord-like prolongations passed up by the sides of the fingers; and that when these were divided, the contraction was immediately removed, the tendons, the bones, and the joints being perfectly sound. He considered these fibrous cords to be digital prolongations of the palmar fascia, and consequently looked upon this membrane as the seat of the disease. Goyrand, who has carefully dissected hands affected in this way, states that these fibrous cords, which he looks upon as the seat of the affection, are not prolongations of the palmar fascia, but are ligamentous structures that extend from its superficial aspect to the sheaths of the flexor tendons, into which they are inserted opposite the second phalanx, being formed by hypertrophy of bands of subcutaneous connective tissue which naturally exist in this situation. However this may be, the fact remains certain that the flexor tendons have nothing to do with this special form of finger contraction, but that it is due entirely to fibrous cords from the digital divisions of the palmar fascia; and as Adams has pointed out, the insertion of these digital prolongations of the fascia into the periosteum of the second phalanx readily explains the drawing down of that bone.

The Diagnosis of cases of digital contraction, so far as the deformity is concerned, is obvious, and requires no comment; so far as the cause is concerned, it is not so easy. Is it tendinous or fascial? When *tendinous* the contracted tendon can be followed up to and above the wrist as a tense cord, the palmar structures being healthy. When *fascial*, the tendon cannot be clearly defined, but the palmar structures are dense, thickened, and incorporated together, forming distinct ridges and sulci.

This true digital contraction must not be confounded with that "arthritic deformans," which often distorts the weather-beaten hands of laboring men and sailors. In these cases all the fingers are bent inwards, and more or less twisted to the ulnar side, so that the hand presents a claw-like appearance, the mischief evidently affecting the joints.

Treatment.—The treatment of digital contractions is purely mechanical and operative. The progress of the disease may be retarded, and some benefit obtained by the use of finger-splints applied to the dorsal aspect and provided with elastic tractors. The kind of operation must be determined by the pathological cause of the disease. As it is now known to be due to fascial changes, the tendon and its sheath must not be touched, but the contracted structures outside them must be cut across. This consists, when the deformity is slight and recent, in dividing each tense digital fascial prolongation by a subcutaneous incision. This should be done opposite the second phalanx, where it is usually most tense, but, if the other finger-joints be affected, a separate section may be required opposite each phalanx. The Surgeon must be careful not to carry his incisions or punctures too deep into the palm, lest the superficial palmar arch or one of its branches be divided. The guide to the commencement of the digital prolongations from the palmar fascia is the *transverse flexion fold* in the palm. This—as Adams has pointed out—corresponds exactly with the line of the metacarpophalangeal articulations, and is of course well in advance of the superficial palmar arch. By keeping the highest incisions near to this line, no danger to this artery need be feared. Should it be found to be impossible to straighten the fingers with such limited incisions, or should the skin be firmly adherent to the subjacent fibrous band, it has been recommended to make a crucial incision through the skin, to dissect the flap back, divide or dissect off the fascial bands from the sheaths of the tendons, and straighten the fingers. As the flexor tendons are not primarily affected they must not be divided. After the operation, the hand should be placed on a dorsal splint and the fingers kept extended.

Adams, recognizing the true pathology of this affection (Fig. 624), has devised and practised a successful means of remedying it by subcutaneous operation. He justly deprecates in such cases all operation by open wound. The plan adopted by Adams consists in making multiple subcutaneous divisions of the fascia and its digital prolongations. For this purpose he uses the smallest possible tenotome—little larger than a cataract-needle; with this instrument, about four punctures and subcutaneous incisions are made to each finger, not operating on more than one or two fingers at a time. The first puncture is made in the palm just above the transverse flexion-crease at a point where the skin is least adherent. By the second puncture, the same cord should be divided between the flexion-crease and the web of the fingers. The third and fourth punctures should be made so as to divide the digital prolongations of the fascia, care being taken not to wound the digital vessels or nerves. Immediate extension is then made, and the fingers kept straight on a padded metal splint.

Fig. 624.—Dupuytren's Contraction (after Adams).

Contraction or bend of the Finger backwards is of very rare occurrence. I have seen only one such case, in a lady in whom the little finger of one hand had a crescentic curve backwards; the ring-finger was also slightly affected. This condition, which was permanent for many years, obstinately resisting all treatment, mechanical and constitutional, appeared to be due to chronic neuritis of the cords of the brachial plexus, consequent on a fall on the back of the head and neck.

Congenital Deformities of the Fingers and Hand are frequently met with.

1. The most common form consists in a **Supernumerary Finger or Fingers**. These are of several different kinds. There is, in the first place, that form of supernumerary finger in which the added digit appears to be simply a continuation of the natural series, so that there are six fingers instead of five. Seven have been met with; and Morand describes a hand having a thumb and six well-formed though somewhat shortened fingers. The supernumerary finger is usually atrophied and shorter than the rest. It is very common in these cases to find both hands equally provided with additional fingers, and the feet with one or more supernumerary toes.

2. The **Thumb** is liable to two malformations—a supernumerary one being in some cases added; in others, the digit being bifid. In the supernumerary thumb (Fig. 625), it will usually be found that there are two small and deformed phalanges; in the bifid one, there is one small and malformed phalanx in each extremity, the two being articulated with the proximal phalanx.

3. The third variety of deformity consists in the development of a *supernumerary finger* on the ulnar side of the hand, so as to constitute a small and deformed additional little finger. All these varieties of deformity of the fingers are more or less hereditary, and may very easily be removed by operation, which is simple and perfectly safe, the supernumerary finger being disarticulated at its base. It is better to do this at as early an age as possible; no good can possibly come of delay.

4. There is a rare variety of congenital deformity of the hand and fingers, in which the fingers are supernumerary, in consequence of a *deep bifurcation of the hand*.

5. In some rare cases, as in that from which the annexed drawing (Fig. 626) was taken, two hands appear to be fused into one. In these cases operation can be advantageously practised.

Besides these, various other kinds of congenital deformity of the fingers are met with. One or more fingers may be preternaturally long or abnormally short, thick, or atrophied; or one finger may be entirely absent.

Fig. 625.—Supernumerary Thumb

Fig. 626.—Apparent Fusion of Hands

The accompanying drawings (Figs. 627 and 628) are correct representations of a remarkable deformity of the hands in a child that was under my care some years ago. The fingers appear to have suffered in some instances complete, in others partial, amputation in utero. They are marked by transverse sulci; others are shortened, and terminate in rounded nodules with a narrow pedicle connecting them with the proximal phalanx.

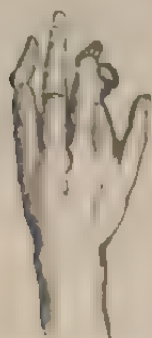

Fig. 627.—Left Hand

Fig. 628.—Right Hand

Arrest of Development of Fingers.

Webbing of the Fingers is occasionally met with. In this condition cutaneous septum unites contiguous fingers. Sometimes the web is confined to one digital interspace and then it is usually that between index and middle fingers. In other cases it occupies two or all three interspaces. The web is a tolerably thick septum of skin, narrow at the base, broader above. It may extend the whole length of the fingers, or in part. The web does not interfere with the movements of the fingers in flexion or extension.

This deformity is readily remedied by operation. The web may be divided in different ways. The plan that I have always successfully adopted consists in separating the fingers widely, and then cutting through the web

is free edge, keeping accurately to the middle line as far as the base of the finger, making the incision longer on the dorsal than on the palmar aspect; or the web may be transfixated at the base, and the incision made forwards. Some Surgeons transfix the base with a ligature or wire, and, bringing it over the free edge, gradually tighten it, and so divide the abnormal bond of union. The objection to this process is that it is slow and painful. After the division of the web, the hand should be put on a splint, and a piece of lint interposed between the separated fingers during the whole process of union, so as to prevent any chance of re-adhesion.

In order to prevent the tendency to gradual union of the raw surfaces advancing from the angle between the fingers towards the tip, it has been suggested, as a preliminary step, to make a puncture through the web, at the base of the space between the fingers, and to pass through this a piece of glass rod or metal, which may be worn until the wound thus made is completely covered by epithelium, the piece of glass acting like an ear-ring in the lobule of the ear. When this healing is complete, the web may be slit up without risk of re-union proceeding from the angle between the fingers.

When the septum is very dense, the following operation, invented by Didot, of Liege, may be advantageously practised. Supposing the index and middle finger to be webbed, the following would be the procedure to be adopted, which is of course equally applicable to any of the other fingers. 1. The Surgeon makes an incision along the median line of the palmar aspect of the index finger, extending the whole length of the web. 2. Two small transverse incisions are now made at the upper and lower ends of this longitudinal incision, extending from it to the ends of the web. 3. The rectangular flap thus defined is dissected back as thick as possible, so that its base corresponds to the mid-line of the web. 4. A corresponding longitudinal

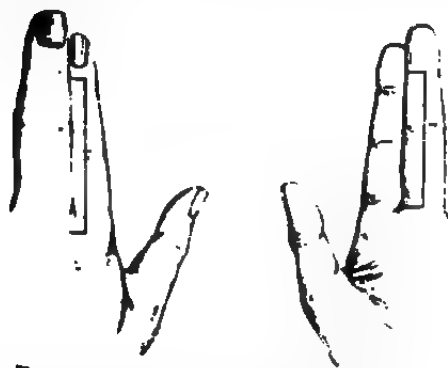

Fig. 629.—Diagram of Flaps in Operation for Webbed Finger, with thick Septum.

Fig. 630.—a. The lines of the two incisions uniting, so as to divide the Web and leave a Flap on each side. b. The Flaps detached from the opposite Fingers to those to which they are adherent. c. The Flaps applied to the Fingers, and covering in the raw and exposed surfaces.

incision is now made along the dorsal surface of the middle finger, but comes rather further down on the hand. The two transverse incisions at its upper and lower ends are next made; the flap thus defined is dissected back, and when the knife reaches the mid-line of the web the two fingers will be found to be separated. 5. The next and last step of the operation is to wrap each flap round the raw surface of the finger to which it continues to be attached, and to fix it *in situ* by three or four points of suture. Thus the raw surface on the index finger will be covered by the flap taken from the dorsum of the middle, and *vice versa*, as is seen in the accompanying diagram (Fig. 629).

In the accompanying cut (Fig. 630), transverse sections of the fingers are shown.

DEFORMITIES OF THE LEG AND FOOT.

Knock-knee.—The deformity termed *Genu Valgum*, **Knock** or **X-Knee**, usually affects both extremities, though it is generally more fully developed in one than in the other. In it the knee forms the apex of a triangle the base of which would be represented by a line drawn from the trochanter to the outer ankle. Knock-knee arises at two periods of life; first during early childhood, when it is usually the result of rickets, and is most frequently conjoined with some curvature of the bones of the leg; and secondly about puberty, when it is due to relaxation of the ligaments, and is frequently the result of carrying heavy weights. At this period it is often conjoined with weak ankles and splay foot. In many cases the flat and everted foot is probably the primary affection. Bock states that out of 221 cases which he examined, 17 originated about the period of the first dentition, and 200 between that age and the 15th or 18th year. Some occupations are said to predispose to it, smiths being especially liable to the disease. In whatever way the deformity arises there is relaxation or stretching of the internal lateral ligament; the biceps, the external lateral ligament, and often the vastus externus are tense; and the patella is thrown outwards. In cases which arise directly from weakness and relaxation of the ligaments, Little states that a distinct gap, often of considerable width, may be felt between the inner side of the head of the tibia and the femur. From an early period in the rickety form, and at a later stage in cases of simple relaxation of the ligaments, the bones become altered in form. The internal condyle is elongated, sometimes, according to Macewen, to the extent of an inch. It is evident that in knock-knee the pressure in standing would be somewhat lessened on the inner side, the weight being unduly thrown upon the outer condyle. It is believed that as the result of this the growth of the outer condyle is arrested, and that of the inner is exaggerated. The lengthening of the inner condyle is not accompanied by a corresponding increase in its antero-posterior diameter, consequently when the knee is flexed the deformity

disappears. In some cases the lowering of the inner condyle is due to a rickety curve in the femur immediately above the articular end. In extreme cases of knock knee the joint is often capable of some degree of over-extension, the leg at the same time rotating outwards.

Treatment.—The treatment consists, in the slighter cases, in applying an apparatus consisting of a well-padded iron stem along the outside of the leg and thigh, this must extend from the trochanter to the outer ankle, being fixed to a pelvic band at the upper part, and into a boot below (Fig. 631). Where it corresponds to the knee it should be provided with a hinge, and should have a broad well-padded strap passing from its under side, over the inner side of the joint, and attached by buckles to the upper part of the stem, in such a way that by tightening these the knee may be drawn outwards. This apparatus should be constantly worn for many months; and, if properly adapted, may effect a cure.

When the deformity is of old standing, and the parts about the outer side of the joint very tense, the biceps tendon may require division. In doing

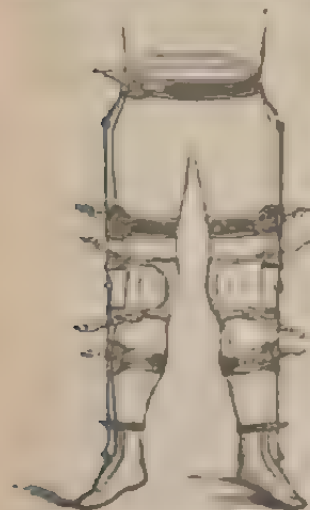

Fig. 631.—Apparatus for knock knee.

this, care must be taken not to injure the external popliteal nerve. In some cases the vastus externus and contiguous portion of the fascia lata also may be advantageously divided, and the apparatus then applied as directed.

In those cases in which the alteration in the bones is such that there is no hope of restoring the limb to its natural position by the simple means above described, the patient must be submitted to some operative procedure, or left to endure his deformity unrelieved.

During the last few years numerous methods have been devised, with the object of straightening the limb. The simplest of these is that of Delore, of Lyons. It consists simply in forcibly straightening the limb; the leg being extended, the Surgeon places his knee against the prominent inner condyle, and grasping the ankle in one hand and the upper part of the femur in the other, he gradually applies sufficient force to bring the limb straight. He continues the force from five minutes to half an hour, till the object is attained. The limb at last yields, a sensation of something tearing being felt. Delore states that the lower epiphysis of the femur is separated, but what actually takes place is somewhat uncertain, and must be left to chance. This method of treatment has been very successful in its inventor's hands, but in this country it has not yielded results equal to those obtained by antiseptic osteotomy.

Antiseptic osteotomy has for its object the restoration of the lengthened inner condyle to its normal level. It is impossible here to do more than mention many of the methods that have been employed with this object. In 1875, Annandale opened the joint and removed the prominent portion of the inner condyle with the saw. This bold operation was completely successful, but since the introduction of simpler methods it has not been repeated. In 1876, Ogston performed, for the first time, the operation of sawing off the inner condyle obliquely by means of an Adams's saw (Fig. 594, introduced obliquely through a puncture made in the skin above the inner condyle. In 1878, Macewen modified the operation by removing a wedge-shaped piece of bone in the line of Ogston's saw cut, but without penetrating so deeply as the articular cartilage, and Reeves at the same time suggested dividing the condyle with a chisel stopping just short of the cartilage. In 1878, Barwell, regarding the deformity not merely as a lengthening of the inner condyle, but as an obliquity of the whole lower epiphysis, divided the femur by a chisel a little above the epiphysis from the outer side, and subsequently after some weeks

Fig. 632.—Knock-knee. *a.* line of division in Macewen's operation. *b.* in Ogston's operation.

Fig. 633.—Macewen's Chisel.

divided the tibia and fibula in the same way about one inch below the articular surfaces. Lastly, Macewen introduced the method of dividing the femur *en masse* immediately above the epiphysis, and, at the present time, this method is almost universally adopted in preference to all others. It has the great advantage of being simple and easy of performance, free from danger, and of not implicating either the epiphysis or the joint. The operation is thus performed. The limb should be laid on its outer side on a bag of wool *en masse*. While the limb is extended a point is taken slightly above the level of the upper margin of the patella, and a longitudinal incision is made in front of the tendon of the adductor magnus, the middle of the incision corresponding to that point. The length of the incision is slightly greater than the breadth of the chisel to be used. The scalpel must be carried directly down to the bone. The chisel is then inserted and turned, so that its cutting edge is at right angles to the incision and to the shaft of the femur. The femur is then divided for more than two-thirds of its thickness, the chisel being taken in and out of the wound as little as possible. The cut in the bone must be parallel to the articular surface of the femur, which will be more obvious than natural, owing to the abnormal length of the inner condyle. The anterior and posterior layers of compact tissue must not be neglected, and when chiselling the posterior extra caution must be used lest the chisel should be driven into the popliteal vessels. When two-thirds of the bone have been divided the remainder is fractured. If the patient be fully grown, and the bone of some size, two or three chisels may be used successively, the first being the thickest. The operation should be performed with all antiseptic precautions, and an antiseptic dressing applied after it. Macewen has always employed the carbolic spray and the carbolic gauze dressings. No sutures should be put into the wound unless it is of unusual size. The dressing may be left unchanged for one or two weeks, unless some discharge shows out from under it, as it may do at the end of the first twenty-four hours. After the operation the limb may be placed on any convenient splint for the first day or two, until it is seen if the dressing requires changing, after which a plaster-of-Paris bandage should be applied. The age at which the operation should be performed has been the subject of much difference of opinion. Experience has shown that if done too early relapse is very likely to take place. As a rule it should not be performed in children under ten. Before that age the deformity can usually be corrected by proper apparatus, aided by the straightening not carried to the extent of separation of the epiphysis. The results of the operation have been extremely satisfactory. In 1880 Macewen had operated on 220 patients for knock-knee, presenting 367 limbs for treatment. In addition to these he had operated on 64 patients, 104 limbs, for bow-legs (*genu varum*), 40 patients (80 limbs), for anterior tibial curves from rickets; one for ankylosis of the hip, and five for ankylosis of the knee. Thus, antiseptic osteotomy had been performed on 337 limbs, in many of these the bones had been divided in more than one place, so that in the 330 patients no less than 835 separate osteotomies had been carried out. In only eight of these cases did the wound fail to heal by first intention, without suppuration. No patient died from the operation, and only three after it, one from diphtheria, one from tubercular meningitis, and one from pneumonia, which had commenced before the operation was done, the patient having been operated on immediately after admission. These operations were in no sense subcutaneous, the wound in every case was at least three-quarters of an inch in length, and air entered freely beside the bone. These results, therefore, cannot but be taken as important evidence of the value of the antiseptic treatment.

Contraction of the Knee-joint.—Contraction of the knee-joint is one of the most distressing deformities to which the human frame is liable. If it be severe, the leg is bent at nearly, or perhaps at quite, a right angle with the thigh. It is fixed in this position, so that the patient cannot put the sole of the foot, nor even the points of the toes, to the ground; hence the limb becomes useless for the purpose of progression, and, from want of exercise, atrophies. But a leg with a badly contracted knee is worse than useless—it is a positive incumbrance; for, as the foot cannot be brought fairly to the ground, the limb projects behind in a most awkward manner, swaying as the body moves round, constantly in the way, and liable to injury. From want of exercise, the nutrition of the limb becomes impaired, the foot is usually cold, the circulation in it is languid, and the toes become liable to chilblains and troublesome ulceration.

In the less severe forms of contracted knee, the inconvenience, though not so great as that just described, is very considerable; for, as the patient can never bring the heel or sole to the ground, he rests insecurely on the tips of his toes, and walks but unsteadily with the aid of a crutch or stick.

Varieties.—This deformity may be of two kinds. 1. It may consist of simple flexion of the leg on the thigh, at a greater or less angle, and with more or less mobility, according to the degree of ankylosis. 2. In addition to this, there may be horizontal displacement of the bones, the head of the tibia being thrown backwards, the femur and patella projecting more than is natural.

In examining a case of contraction of the knee-joint, the patient should be placed on his face, with the thigh extended. The leg on the affected side will then be raised more or less perpendicularly, and the amount of contraction may be judged of by the angle that it forms with the thigh. The degree of mobility also may readily be ascertained. In this way a more correct idea of the amount of contraction can be obtained than by examining the patient whilst lying on the back, when, in consequence of the thigh being flexed on the abdomen, the extent of the angular deformity cannot be so well determined.

Causes.—Contraction of the knee-joint may arise from a great variety of pathological conditions. Some of these are altogether external to the joint, being seated in the nerves or muscles of the limb; whilst others, and the majority, consist in some morbid change that has taken place within the joint itself in its ligamentous or osseous structures. As the contraction depends on such very varied causes, the *Treatment*, having reference to the cause as well as to the actual morbid conditions, must be equally diversified.

Contraction from Nervous Irritation is usually associated with general hysteria, of which it is but a local symptom, and commonly occurs in girls and young women. In this form of contraction there is no evidence of disease within the joint; no redness, swelling, or other sign of inflammation; but there are great pain and tenderness about it. This pain, as usual, in hysterical cases, is superficial and cutaneous. It is not confined to the articulation, but radiates to some distance beyond it. Any attempt at straightening the limb not only greatly increases the pain, but also calls the adjoining muscles into such forcible action that it is impossible to improve the position. These local symptoms are connected with the ordinary signs of a hysterical temperament, with spinal irritation, and often with uterine derangement.

The *Treatment* of these cases of hysterical contraction of the knee is simple. The first thing to be done is to straighten the limb. This can be effected only by putting the patient under the influence of an anæsthetic, when, all sensibility being suspended, the muscular opposition, which is partly volun-

tary, and no doubt in some measure reflex, is no longer called into action, and the limb falls of its own accord almost into a straight position, in which it must be retained by means of a back splint, lest the retraction repeat with returning consciousness; and then, the hysterical condition being removed by treatment calculated to improve the general health, the tendency to the return of the deformity will be obliterated.

We occasionally see contraction of the knee from spasmodic action of the hamstrings, produced by some irritation applied to the nerves at a distance from the part. Just as spasm of the internal rectus muscle of the eye occasions squint, so long as the irritation that gives rise to the spasm lasts, so there may be spasm of the hamstrings, with contraction of the knee as a consequence.

Most commonly, however, the joint itself is at fault, either in consequence of subacute inflammation within it, or of the permanent changes induced by former inflammatory attacks.

Contraction from Inflammation of the Knee.—In inflammation of the knee, the patient naturally and instinctively places the limb in the semi-flexed position, as being that in which there is least tension exercised on the structures that enter into the joint, and consequently that which is most congenial to his feelings. This position, which is immediately assumed on the occurrence of acute and active inflammation in the joint, comes on more gradually in cases of subacute inflammation; and here the symptoms of disease in the joint may be so slight that the contraction may be considered the chief ailment, and engross too exclusively the Surgeon's attention.

Chronic Contraction.—The next class of cases that we have to consider are those of a more chronic and intractable kind, lasting often for years, dependent upon structural lesions of a deep and important character in and around the joint, and requiring very active surgical interference for their cure. Those chronic forms of contracted knee appear to range themselves in three distinct varieties, being dependent on: 1. Consolidation and contraction of the Ligamentous Structures in or around the joint; 2. Permanent Contraction of the Muscles, with or without the last-named combination; and 3. Osseous Ankylosis. Each of these varieties will require separate consideration, as each demands a special mode of treatment for its cure.

1. Those cases of contraction of the knee that depend on *Consolidation of the Ligamentous Structures* in and around the joint, resulting from former inflammatory attacks, are not only the most numerous, but the most readily amenable to treatment. When the structures outside the joint, such as the capsule and ligaments, are the parts chiefly affected, the inflammation has usually been of a rheumatic character. When the internal structures have been disorganized, and fibrous bands have formed within the joint, the inflammation has generally been stumous. In these cases the knee is usually fixed at or near a right angle, and is capable of but very limited motion—to such a degree only, in most instances, as will allow the foot to move through two or three inches. The hamstring muscles are not tense unless the knee is extended to its utmost; and, indeed, in some cases they are flaccid, and feel soft. Not unfrequently the leg can be extended up to a certain point with as much freedom as in the natural state, and then further movement is checked by a sudden stop. If this be not dependent on the tibia coming into contact with an ankylosed patella, it is owing to shortening of the ligament of Winslow, or of the anterior crucial ligament, or to the formation of adhesions within the joint. In this form of contraction, the knee is often much distorted, in consequence of the head of the tibia being partially dislocated backwards, the femur having its axis directed more or less on one side, most commonly inwards, constituting a kind of

genu valgum. In fact, in these cases the distortion of the limb is of a three-fold character; there are, 1, contraction in the angular direction backwards; 2, displacement of the head of the tibia backwards from the lower end of the femur, which projects considerably forwards; and, 3, rotation of the leg and foot outwards. The angular contraction is dependent upon adhesions in the joint, and on the gradual tendency to flexion that all inflamed joints assume. The partial dislocation backwards is dependent on softening and consequent relaxation of the posterior crucial ligament, and partly, also, of the ligamentum patellæ or of the lateral ligaments. When the head of the tibia is displaced backwards, it will sometimes be found that the ligamentum patellæ has been either partially absorbed, and thus weakened, or that it is elongated, the patella being drawn upwards or to one side. In either way, the action of the extensor muscles of the thigh upon the head of the tibia is weakened; and that bone, being consequently brought under the influence of the hamstrings, which also act more advantageously in the flexed position, is drawn backwards (Fig. 634). In those cases in which there is lateral

Fig. 634.—Chronic Contraction of Knee-joint; Head of Tibia drawn backwards

rotation of the tibia, the faulty position arose either from the attitude that limb was allowed to assume during the progress of the disease in the joint, or the leg was rotated outwards by the action of the biceps overcoming that of the inner hamstrings.

When the knee has been chronically contracted for some length of time, the ligamentum posticum becomes permanently shortened, from adhesion of the sides of the folds into which it is thrown by relaxation. And a similar shortening takes place also in the anterior crucial ligament when it is relaxed by displacement of the head of the tibia backwards. Hence the condition of these ligaments offers the chief obstacle to extension.

Treatment of Contraction of the Knee.—Extension of the limb will prove sufficient when there is simple angular contraction. This may be done either gradually by means of the screw-splint behind the knee, or forcibly and at once, under the influence of anæsthetics. I prefer the latter method, not only as being the speediest, but as being perfectly safe and effectual. The mode of effecting forcible extension is as follows: The patient being fully under the influence of an anæsthetic, and lying on his face, the Surgeon, standing above him, seizes the foot of the affected limb with one hand, whilst with the other he steadies the limb just above the knee. He now extends the leg gradually but forcibly; as it comes forwards, the bands of adhesion in and around the joint will be felt and heard to give way with loud snaps and cracks, distinctly audible at some distance. Should there be much resistance within the joint, the surgeon may apply his own knee or elbow to

the upper surface, and thus increase the force with which the limb is pressed upon. In this way, I have never found any contractions of the kind to be under consideration able to resist the surgeon's efforts, nor any difficulty in effecting at once the extension of the limb. Nor have I ever seen any evil consequences result; indeed, it is surprising to what an amount of force a joint that has been contracted for any length of time may be subjected without inconvenience. In these cases it would appear as if the synovial membrane lost its tendency to inflame, just as is the case with serous membranes that have been the seat of chronic inflammation and its consequences. Beyond some pain for a few days, and slight heat, easily subdued by cool evaporating lotions, I have never seen any ill-results arise, but care must be taken that no inflammatory action is going on within the joint at the time of this manipulation, for, if such action were present, the operation would certainly be followed by injurious results. After extension has been

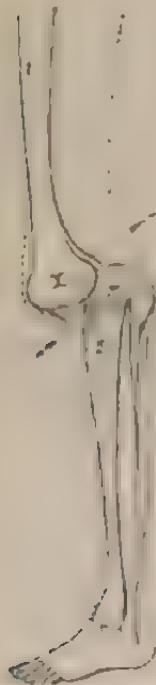

Fig. 635. Knee joint after Extension. Head of Tibia thrown Backwards.

Fig. 636. Apparatus for retaining Position after Extension of Contracted knee joint.

made, the limb should be fixed on a long splint, well padded or on a Thomas's knee-splint, some evaporating lotions applied, and the patient kept in bed for a few days, after which, with the aid of a starched bandage, he may walk about.

When the triple displacement which has already been referred to exists

viz., angular contraction, displacement of the head of the tibia backwards, and rotation of the limb outwards—simple extension is no longer sufficient to remedy the deformity. In these cases the hamstring tendons often require division, generally on both sides—sometimes only the external one; and extension may then be effected, either forcibly, or by the gradual and slow action of rack and pinion apparatus. When extension is complete, the backward displacement of the head of the tibia may still occasion considerable deformity and weakness of the limb (Fig. 635). This condition is best removed by the use of the instrument of which the sketch on the preceding page (Fig. 636) is a good representation; it was designed and constructed by that excellent surgical mechanic, Mr. Bigg. The diagram represents a limb with the tibia displaced backwards, the angular contraction having been remedied. In the centres of the lower end of the thigh-bone and of the head of the tibia, two letters (X and Z) are placed to designate the axis of each bony head, beneath and above which the displaced joint has formed its abnormal axis. The dotted lines represent the leverage formed by the cylindrical surface of the tibia and thigh-bone. The arrows are placed in such a direction as the bones would take in resuming their normal position. It will readily be seen that any instrument capable of acting in the mechanical directions shown by the arrows, would not only accomplish the restoration of the joint, but extend, if contracted, the extremities of both femur and tibia.

An additional advantage that this instrument possesses over any other with which I am acquainted, is the application of spring-power, by means of which flexion of the knee becomes an element towards the restoration of its utility. Instead of muscular action being arrested, and atrophy of the limb being thus produced, movement is conducive to the perfect action of the apparatus; so that the patient experiences but little inconvenience from its use, all the ordinary positions assumed by the knee in walking, sitting, or standing being preserved.

By this form of apparatus, then, three important points are secured: viz., replacement of the head of the tibia, extension of the angle of the leg, and free muscular action during the period of treatment.

In Fig. 636, A and B are two levers, composed of metal, corresponding in their direction to the perpendicular position of the thigh-bone and tibia. C and D are two axes, placed exactly coincident with the centres of the articular ends of the bones. E and F are two powerful springs, acting in opposite directions; viz., in those indicated by the arrows in Fig. 635. Thus F presses the lever B in a forward direction, bearing the end of the tibia forward, whilst E presses the lever A in a backward direction, bearing the end of the thigh-bone backward. As C and D are found acting above and below the actual axis of the knee-joint, they mutually influence the point formed by the apposition of the heads of the tibia and thigh-bone; and as it has already been explained that the thigh-bone really offers a fixed resistance, and the tibia moves beneath it, the head of the latter bone is brought forward in a semicircular direction consequent on the upper centre (C) being a fixed point, and the lower centre (D) rotating around it. G is an elastic knee-cap; H, a padded plate. When the ligaments are tense, there is a chance of pressing the anterior surface of the tibia against the posterior surface of the thigh-bone. This is readily obviated by having the shaft A made to elongate, when the centre (C), being a little lowered, pushes the lever B downwards, carrying the tibia with it, and thus separating the osseous surfaces of the joint.

2. The next class of cases of contracted knee that we have to consider is that in which the *Hamstrings are Contracted*, either alone or in addition to

those results of chronic inflammatory action within the joint that have just been described. In these cases the hamstrings will be found to be tight and in proportion as the leg is extended on the thigh, they will become more tense, until at last all further extension is resisted, apparently by their traction, and not by any sudden check or stop within the joint itself.

Division of the Hamstring Tendons is in ordinary cases an attitude of operation as any in surgery, unattended by any difficulty, provided the Surgeon introduce the tenotome close to the side of the tendon to be divided, and cut in a direction from the popliteal aspect towards the skin. The outer hamstring will usually be found to be the most tense, and should first be divided. In doing this, the peroneal nerve might appear to be in danger, but this may be avoided by keeping the sole of the tenotome well against the inner edge of the biceps tendon, then turning the edge outwards when passed deeply enough. The semitendinosus next requires division. The semimembranosus need not often be cut across. After the division of the tendons, tense aponeurotic bands will not unfrequently be found to stretch along one or both sides, or perhaps down the centre of the popliteal space. This may lead to the idea on the part of the Surgeon that he has not truly cut the tendons across; but this is an error. The bands alluded to are condensed sharp-edged prolongations of the fascia lata, formed during the period of contraction of the joint by the shrinking and thickening of this membranous expansion. Such condensations as these had better be left untouched, as they will readily stretch out under gradual extension or be ruptured by forcible traction of the limb. It, on the other hand, the Surgeon be tempted by their apparently superficial and safe position to proceed to their division, he may be brought more closely into contact with the popliteal vessels than is desirable or safe. In these cases, the anatomical relations of parts are so much altered by the narrowing of the popliteal space, and by the projection of the head of the tibia backwards, or by its lateral rotation, that the Surgeon is unable to calculate with sufficient nicety the precise position of the large vessels and nerves in the neighborhood of which he is about to act; and he may thus injure one or other of these at a time when he thinks that he is operating at a safe distance from them.

After division of the hamstrings, the knee does not commonly come readily into the straight position, owing to the shortening of the posterior ligament, and gradual extension, by means of proper apparatus, will be required to overcome this and to stretch the adhesions within and around the joint.

Contraction with Lateral Displacement is not unfrequently met with. In these cases the knee is contracted more or less in the angular direction, but, in addition to this, the lower end of the thigh-bone is directed inwards and perhaps somewhat forwards, and the tibia is rotated outwards, carrying the foot with it. There is thus a triple deformity—angular, nasal, and rotatory. I believe the angular to be the primary deformity, and the nasal and rotatory to be secondary to this, arising partly from the efforts of the patient to walk by resting on the point of the great toe, and throwing the thigh inwards in order to effect this, and partly from the action of the biceps rounding the leg outwards.

The *Treatment* of these cases is not very satisfactory. The obstacle to the restoration of the normal position of the joint is dependent, so far as the angular contraction is concerned, on shortening of the ligamentum posterum, and the rotatory displacement is kept up and rendered intractable by shortening of the anterior cruciate ligament. Mere extension of the limb, whether gradual or forced, may counteract the angular deformity, but it will not only leave the other displacements uninfluenced, but may actually increase the displacement of the tibia backwards and the rotation of the leg outwards.

A leg-and-thigh splint, such as is shown in Fig. 636, but having, instead of the springs, a rack-and-pinion apparatus working on three centres, so as to extend the limb, abduct the knee, and rotate the leg inwards, is the only contrivance by which this deformity can be counteracted, and the limb restored to shape.

In reference to the treatment of these various deformities of the extremities, it may be stated generally that it is much easier to rectify faulty position than to restore mobility. The first may always be done by the various means that have been enumerated; the latter can be effected only, if at all, by long-continued efforts on the part of the Surgeon, by passive motion, frictions, shampooing, etc., aided by properly constructed apparatus.

In ankylosis of the knee, after extension has been made, and the limb brought straight, the question arises as to whether mobility of the joint should be encouraged, or the limb kept straight and made stiff. The answer to this question will greatly depend on conditions of the muscles of the thigh. If the quadriceps extensor exhibits electric irritability, then, if the state of the joint admit it, motion may be attempted. If the muscle be insensible to the stimulus, then the joint had best be kept stiff.

3. **Osseous Ankylosis of the Knee** is not of very frequent occurrence. It is usually the result of traumatic inflammation of the joint. If the limb be straight, no operation will be advisable; if it be bent, so that the patient cannot put the foot to the ground, the only remedy will be an operation. Rhea Barton, of Philadelphia, in 1835, proposed an operation for restoring the straight position of the limb in cases of complete osseous ankylosis of the knee-joint with angular deformity. The proceeding consists in excising a wedge-shaped piece of the shaft of the femur above the condyles, not including the whole diameter of the bone, then fracturing the undivided portion, and so bringing the limb into a straight position. Birch, of New York, in 1844, modified this operation by sawing out a wedge-shaped portion, consisting of the condyles of the femur, the patella, and the head of the tibia. According to Gross, these two operations have been done in all in 21 cases, of which 4 proved fatal by pyæmia. In one case, that of Reil, the femoral artery had to be tied for secondary hemorrhage from the popliteal on the fifteenth day; but the patient made an excellent recovery with a useful limb. Brainard, of Chicago, in 1854, proposed a simple and less severe method than either of the above, for the remedying of angular osseous ankylosis of the knee. It consisted in drilling the femur subcutaneously and then fracturing the bone. This operation was first done by Pancoast in 1859, and since then has been successfully practised by Brainard, Gross, and others, who have extended it to subcutaneous perforation of the joint and to separation of the patella.

The drill used for this operation consists of a steel shaft $4\frac{1}{2}$ inches long, fitted with a solid and rounded handle (Fig. 637). The point is $\frac{1}{4}$ th of an

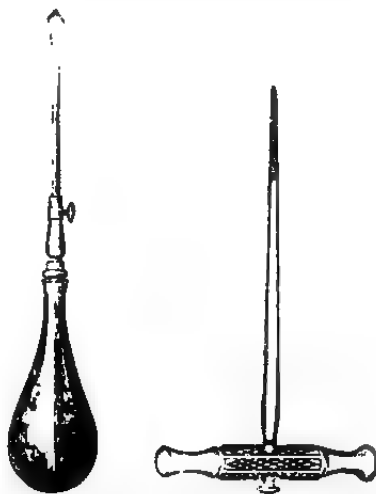

Fig. 637.—Drill for Ankylosed Knee. Fig. 638.—Drill for Ankylosed Joint.

inch in breadth, and has on each side an oblique groove with cutting edges, so that it acts as a gouge as well as a drill. The interior of the obliterated articulation is reached by making an incision about half an inch long on the outer side of the limb, at the line of junction between the condyles of the femur and the tibia. The drill is then worked through, until its end can be felt under the integuments on the opposite side of the limb. The instrument must now be worked in such a manner as to break down the osseous adhesions between the femur and the tibia on the one hand, and the patella on the other. The patella is sometimes best loosened by using the drill as a lever. When the bones have been sufficiently perforated in different directions, the limb must be extended, when the remaining osseous connections will give way with a cracking noise. The wound in the integument is then closed with silver sutures and collodion, and the limb laid on a pillow. In three or four days it may be put in a McIntyre splint, and gradual extension practised, the soft parts posteriorly slowly yielding. Bony union will then take place; but it is a decided advantage when the limb is stiff for the knee not to be quite straight, but slightly flexed, so that the leg may be about an inch shorter than the opposite limb.

This operation, it will be seen, is in many respects superior to those of Barton and Buck; for whilst bringing the limb into an equally good position, it does so by a comparatively slight and subcutaneous procedure, unattended by any danger of hemorrhage or of complications arising from an extensive open wound. The nine cases in which it has been done were all successful. These various perforating operations appear hitherto to have been confined to the knee-joint. But there can be little doubt that they might advantageously be extended to other joints affected by osseous ankylosis, more particularly in the hip. In angular contraction of the knee-joint with dislocation of the tibia backwards, Volkmann has corrected the deformity, by cutting across the femur just above the condyles, and in one case by doing the same to the tibia just below its head. This he recommends to be done with a chisel, the wound being dressed antiseptically.

Ankylosis of the knee in the *straight position* interferes comparatively little with the utility of the limb. It is, however, desirable, when practicable, to restore the mobility of the joint. The possibility of doing this will depend on the degree of ankylosis. If this be osseous, or even if densely fibrous, little can be done; but if the rigidity depend chiefly on condensation of the capsule, and fibroid induration outside the joint, much may be effected by the use of properly constructed apparatus. This should be of two kinds:—1. A leg-and-thigh piece securely laced on to the limb, having an angular joint opposite the knee, and connected posteriorly by a strong band of vulcanized India-rubber, the elastic tension of which is constantly striving to overcome the straightened limb by flexing it backwards; and, 2, a similar apparatus, with rack and pinion, instead of elastic, by which the knee can be forcibly flexed once at least in the day.

Ankylosis of the knee in the *angular position forwards*, so that the leg is over-extended upon the thigh, is very rare. Indeed, I am acquainted with only three preparations illustrating this deformity—one in the museum of University College, one in that of St Thomas's Hospital, and another exhibited by Adams to the Pathological Society, from a limb amputated by Grant, of Canada, in which this condition occurred to a young man as a consequence of a wound of the joint some years previously.

Deformities of the Bones of the Lower Limb from Rickets. The distortions of the bones of the leg arising from rickets have already been alluded to in the chapter on diseases of bone. It is needless here to add more than mention that antiseptic osteotomy has been applied of late years with

great success to the treatment of these deformities. It is seldom that any operation beyond that already described for knock-knee is required in the femur. In the tibia the curve is most commonly outwards and forwards, often to such an extent as seriously to cripple the patient. In these cases a wedge-shaped piece of bone is often removed from the most prominent part of the curve, but as good a result can usually be obtained by simple division of the bone by the chisel and mallet, used in the same way as in the operation for knock-knee. If necessary, the same bone may be divided in more than one place, either simultaneously, or the second operation may be deferred till the patient has recovered from the first. In complicated cases of knock-knee with rickety curves of the femur and tibia, Macewen has performed as many as ten osteotomies simultaneously on the same patient. If proper antiseptic precautions are adopted, the danger of these operations is very slight, as may be seen from the result of Macewen's practice (p. 510).

CLUB-FOOT.—Deformities of the foot may affect either one or both of the extremities. They may be congenital or acquired, and may occur in either sex, but appear to be more common amongst boys than girls. There are four primary varieties of club-foot and two secondary ones. Of the four *primary* forms, in two the deformity is in the antero-posterior direction, in the sense of flexion and of extension: *Talipes Equinus*, in which the heel is drawn up and the toes pointed downwards; and its antithesis, *Talipes Calcaneus*, in which the heel is pointed downwards and the foot and toes drawn up. In the remaining two forms the deformity is lateral, the foot being adducted and twisted inwards in *Talipes Varus*, and abducted and twisted outwards in *Talipes Valgus*. The four primary forms of club-foot correspond with and are dependent on a permanent condition of one or other of the four simple movements of which the foot is susceptible at the ankle-joint.

Thus in *Talipes Equinus* the foot is extended, the heel being raised, and the dorsum pointing downwards in a line more or less direct with that of the anterior part of the leg. This is due to permanent contraction of those muscles that are inserted into the os calcis through the medium of the tendo Achillis. In *Talipes Calcaneus* the foot is drawn up and the heel depressed, so that the dorsum forms an angle more or less acute with the front of the leg. Here the *tibialis anticus* is the muscle chiefly at fault. In *Talipes Varus* the foot is adducted forcibly, and the inner side of the sole raised sometimes to a right angle with the ground; this is due principally to the combined action of the *tibialis posticus* and *tibialis anticus*; and in *Talipes Valgus* we have the converse—abduction of the foot, and raising of the outer side of the sole, due to the action of the peronei.

Besides these four primary forms, there are two secondary varieties of club-foot: *Talipes Equino-varus*, in which the heel is raised and the foot drawn inwards, and *Talipes Calcaneo-valgus*, in which the heel is drawn down and the foot turned out. The *Talipes Equinus* and *Varus* are commonly associated, because in these forms the flexor and adductor muscles, viz., the strong muscles of the calf and the *tibialis posticus*, those that are supplied by the posterior tibial nerve, are contracted. Again, the *Talipes Calcaneus* and *Valgus* are associated, because in these the extensor and the peroneal muscles, those supplied by the external popliteal nerve, are the seat of contraction. In some forms of club-foot, especially in the *varus* and *equino-varus*, it will be found that the muscles antagonistic to those that are contracted are in a state of atrophy and defective innervation—in this case the extensors on the anterior part of the leg and the peronei. In such instances as these, electricity becomes an important adjunct to the more directly surgical and mechanical treatment.

In infants with talipes, Sayre begins treatment at once, as soon as possible

after birth, by drawing the foot into position. When this is done, it becomes quite white and bloodless. The traction must then be discontinued, but be resumed again in a very short time, and so repeated. After a time the limb may be fixed in proper position by the application and traction of plasters; and thus if the talipes be not cured, it may very early be much anchored and rendered more fit for operative treatment.

Pathological Changes.—On dissecting a foot affected by talipes, it is seen that but little alteration has taken place in the condition of the bones. In some preparations of this kind which are in the University College Museum, these are nearly normal (Figs. 640, 644). Indeed, in the equinus and calcaneus, they are scarcely if at all altered; but in talipes valgus, if of old standing, the astragalus will generally be found atrophied, particularly about its head, which may be somewhat twisted, and the navicular and cuboid bones will be seen to have undergone similar changes. The ligaments are necessarily somewhat altered in shape, being lengthened on the convexity, and shortened on the concavity of the foot; the direction of the tendons is altered, and the muscles, not only of the foot, but of leg and thigh, are generally atrophied from disuse, so that the limb in cases is withered and shortened; indeed, so great an incumbrance may occasionally become under these circumstances, that amputation of the limb may be insisted on by the patient, and with propriety be performed by the Surgeon.

Talipes Equinus is characterized by elevation of the heel, and tension of the tendo Achillis. In slight cases the heel may merely be raised a few

Fig. 639. Talipes Equinus.

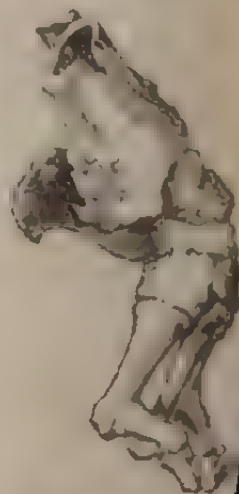

Fig. 640. Bones in Talipes Equinus.

above the ground, and it will be found on examination that it enters forwards to an acute or even to a right angle with the leg. In severe cases the foot may be extended in nearly a straight line with the leg, so that the patient walks on his toes, which are placed at a right angle to the leg (Figs. 639, 640). In this deformity there is no lateral displacement. As Thompson it is never congenital. It most commonly arises from a lesion of the nervous system during teething. In adults, as well as in children, it may come on from some disease, such as an abscess in the calf.

which the gastrocnemius muscle is crippled, shortened, and contracted. It is the most important, and at the same time the simplest in itself, of all the forms of club-foot; it commonly complicates *T. varus*.

The *Treatment* consists in *dividing the tendo Achillis*, and bringing the heel well down. The tendo Achillis is best divided about an inch above its insertion into the os calcis. The limb should be placed on its outer side. The assistant then relaxes the tendon slightly while the Surgeon slides a tenotome beneath it from the inner side; the assistant then makes the tendon tense, and the Surgeon proceeds to divide it, using the knife as a lever, the fulcrum being the edge of the malleolus. The Surgeon must keep the fingers of his left hand on the tendon to feel that the knife does not approach the skin too closely. As the section proceeds, he will hear the tendon creaking as its fibres are successively cut through. The division may be safely made from the cutaneous surface if it be preferred. The tendon must be made tense, and the point of the tenotome entered through the skin close to its anterior surface; the foot is then fully extended, while the

Fig. 641.—Apparatus for use after Division of Tendo Achillis for Paralytic Equinus.

Fig. 642.—Talipes Calcaneus.

Surgeon pinches up the skin, and passes the tenotome between it and the tendon. He then turns the edge of the knife to the tendon, while the assistant forcibly flexes the ankle. No sawing or free cutting is required if the knife have been entered sufficiently far forwards. With ordinary care, there is no risk of wounding the posterior tibial artery.

In cases in which the deformity is due to paralysis of the tibialis anticus and extensors of the toes, a condition very frequently met with as the result of infantile paralysis, the apparatus represented in Fig. 641 fitted to a boot, will be found of great use in preventing the return of the contraction after division of the tendon.

Talipes Calcaneus is a rare variety of club-foot. In it the heel is depressed, the toes and anterior part of the foot being elevated (Fig. 642); it is usually, I believe, congenital—in one case under my care, however, that of a girl twelve years of age, it was acquired. It arises from contraction of the extensors consequent upon loss of power in the flexors. It is sometimes met with in cases of spina bifida.

Treatment.—In order to bring down the foot, the tibialis anticus, the extensor communis, the extensor pollicis, and the peroneus tertius tendons, may all require to be divided as they pass over the dorsum; a straight splint should then be applied, and the foot drawn down to it. A minor degree of

this affection consists in a peculiar projection upwards of one or two of the toes, associated with some tension of the extensor tendons; by dividing these and keeping the foot on a flat splint, the deformity may commonly be corrected. In some cases, however, the toe is so prominent, and the contiguous ones are squeezed under it in such a manner, that the foot is completely crippled, and amputation of the displaced digit is required in order to restore the utility of the member.

Talipes Varus.—In this deformity the foot is twisted inwards, the inner side of the sole is raised, and the sole is contracted; the patient walking on the outer side of the foot, where the skin covering the tarsal end of the 5th metatarsal bone often becomes excessively dense and firm, and a bursa occasionally forms (Fig. 643). In most cases there is some elevation of the toes.

Fig. 643.—Talipes Varus.

Fig. 644.—Bones in Talipes Varus.

the affection partaking somewhat of the character of talipes equinus. It is the most common form of congenital deformity, both feet being found equally affected, but it may be non-congenital, dependent on infantile paralysis of the extensors, and then is often limited to one foot.

The *Treatment* consists in the successive division of the tendons of the *tibialis anticus* and *tibialis posticus*, which are the muscles principally at fault. After these have been cut across, the *tendo Achillis* should be divided, but its section should be made last, as it steadies the foot, and thus facilitates the division of the tibial tendons. Some Surgeons delay division of the *tendo Achillis* for some weeks, till the lateral displacement of the foot has been remedied. In most cases the plantar fascia is contracted, and requires division wherever it feels tense and projecting. In the section of the *tibialis posticus* tendon behind the ankle, there is much danger of wounding the posterior tibial artery, which lies close to it.

The best way to avoid this vessel is, as Tamplin recommends, to puncture the sheath with a sharp tenotome introduced close to the tibia, immediately above the malleolus. In the adult or young children past the age of infancy a small point of bone can be felt in this situation, which marks the upper limit of the groove in the malleolus in which the tendon lies. The puncture should be made above this, otherwise the knife cannot be passed under the tendon. After the sheath has thus been opened by a puncture, a blunt tenotome is introduced, care being taken not to use so much force as to push it through the sheath on the opposite side. The tendon is then divided in the usual way. If the operation be performed too high up the limb the *flexor longus digitorum* will be divided with the tendon of the *tiabinus posticus*, but

this is a matter of little moment. Unless great care be taken in cutting through the tendo Achillis, there is also some risk of wounding the artery; as, in bad cases of varus, these two structures lie close together, the tendo Achillis being drawn out of the median line towards the inner ankle. Indeed, in one instance I have seen the posterior tibial artery punctured during the division of this tendon, or rather in an attempt to divide some tense bands that lay beneath it; the bleeding, which was very free and in a full jet, was, however, readily stopped by pressure, no bad consequences resulting. The

proper plan of treatment, when such an accident occurs, is, when the artery is merely punctured, to cut it completely across, and then to apply firm pressure by means of a pad and bandage over the bleeding orifice. Tamplin states that he has seen no ill-effects follow this accident. If a circumscribed false aneurism form, it must be laid open, the clots turned out, and the vessel tied. No extension of the foot should be practised for some time in such cases, lest the coagulum be disturbed.

The tibialis anticus must be divided at the point marked in Fig. 645. The tenotome must be passed from the outer side to avoid any risk of wounding the dorsal artery of the foot.

In ordinary cases of varus, after a lapse of four or five days, Scarpa's or

Little's shoe, or Aveling's talivert (Fig. 646), a most ingenious and useful instrument, allowing every movement necessary in club-foot, may be applied; or the foot may be well abducted by means of a wooden splint, fixed to the outer side of the leg, and provided with pegs, so placed that the toes can be drawn up, and the foot well turned out, by rollers and tapes attached to them.

In some cases the foot may advantageously be put up in plaster of Paris. In order to do this, it is first bandaged with a narrow flannel roller. The assistant then grasps the leg firmly above the ankle, while he holds the foot in as nearly as possible the normal position by a narrow loop of bandage passed round the ball of the great toe, and held to the outer side. The

Fig. 646.—Aveling's Talivert.

plaster is then applied, and the foot held in position till it has set. The bandage should be changed about every two weeks, the foot being each time drawn a little more into its proper position.

In spite of all treatment, however, a considerable proportion of cases of congenital talipes equino-varus are at most only partially relieved. In such cases, as the child grows up the muscles fail to develop, and the bones become altered in form so as to adapt them to their abnormal position. In such extreme and incurable cases, various operations have been recommended to enable the patient to bring the sole of his foot to the ground. Many years ago, Little suggested the removal of the cuboid in order to assist in overcoming the adduction of the anterior part of the foot. This operation was performed with success by Solly, in 1857, but did not come into general use. In 1872, Lund, of Manchester, removed the astragalus from each foot of a child, with the result of obtaining considerable improvement in the position of the feet. In 1876, R. Davy repeated the operation in several cases, obtaining good results, but was not able to dispense with prolonged use of apparatus afterwards. In 1876, Davies-Colley recorded a case in which he removed a wedge-shaped piece of the tarsus of sufficient size to allow of the anterior part of the foot being brought into a straight line with the posterior. The operation was performed by a long incision on the outer side of the foot from the middle of the os calcis to the middle of the fifth metatarsal bone. From the middle of this another was carried across part of the dorsum. The cuboid was first removed, after which a wedge-shaped portion of the tarsus was removed "without paying any regard to its articulations." The bones removed included the whole cuboid, parts of the os calcis, of the three cuneiform bones, nearly all the scaphoid, and a part of the head of the astragalus. This operation has been repeated by R. Davy and others with the most satisfactory results. In Davies-Colley's case, the patient could jump and hop six months after the operation. If the heel is much drawn

up, the tendo Achillis can be divided after the operation. Davies-Colley found the most convenient apparatus, during the early part of the after-treatment, to be "a back-splint extending from the middle of the thigh to within four inches of the heel. To the distal end of this was fastened a transverse bar of wood, terminating on either side in short upright bars, to which the forepart of the foot was attached by means of strapping."

Talipes Valgus (Fig. 647) is the antithesis to varus. It is not so frequent a deformity as the other varieties of club-foot. It commonly affects only one extremity, and is occasionally congenital. True valgus arises sometimes from contraction of the peronei, but more commonly from paralysis of their opponents. The foot is everted, the arch is obliterated, so that the sole becomes flattened. The anterior part of the foot is displaced outwards at the calcaneo-cuboid and astragalo-scaphoid articulation, and the scaphoid is partially dislocated outwards, so that the head of the astragalus projects at the inner side of the foot. The toes and anterior part of the foot are often raised so as to constitute the variety termed *Calcaneo-valgus*. The most marked forms of this variety are met with when the muscles of the calf, the *tibialis posterior*, and the flexors of the toes are paralyzed. The projection of the heel backwards is obliterated, and the outer side of the foot curved round so that the little toe is approximated to the point of the heel.

In extreme cases of calcaneo-valgus, the arch of the foot is sometimes increased, the heel being pointed down, and the foot sharply bent at the transverse medio-tarsal articulation, so as to bring the toes to the ground.

Treatment.—In the earlier stages of acquired talipes valgus, the deformity may often be remedied by putting the patient under the influence of an anæsthetic, forcibly drawing the foot inwards so as to overcome the tension of the peronei muscles, fixing it in a Dupuytren's splint, and afterwards restoring the arch of the foot by a convex sole in the shoe.

In the more confirmed cases, the treatment consists in the division of the tendons of the *peroneus longus* and *brevis*, behind the outer ankle; and of that of the *extensor communis* on the dorsum. Scarpa's shoe may then be applied, and the arch of the foot restored by wearing a pad under the sole for some considerable time.

Flat or Splay Foot. **Spurious Talipes Valgus** is a condition frequently met with in young adults. It is predisposed to by those constitutional conditions that have already been described as favoring the development of curvature of the spine, but the determining cause is most frequently over-fatigue of the foot from long-continued standing, and from carrying heavy weights, or from a slovenly habit of walking by sliding rather than raising the feet, or twisting the foot so as to press upon the inner side. Girls of a tender age being allowed to carry infants, boys set to heavy work beyond their strength, shop-boys and girls mercilessly kept upon their feet for too many hours, will early develop this deformity. When both feet are affected, there is usually knock-knee as well. The disease is due to a weakness of the muscles in the sole of the foot, and to relaxation of the ligaments by which the arch is maintained, especially the *ligamentum longum plantæ*, and the inferior calcaneo-navicular ligament. As the result of this, the arch of the foot gradually sinks, so that the sole becomes perfectly flat. As the disease

Fig. 647.—Talipes Valgus.

advances, a tendency to eversion of the foot takes place. At the same time, owing to flattening out of the arch, the inner side of the foot becomes lengthened, while the outer side, which is naturally but slightly arched, is but little altered. In consequence of this, the anterior part of the foot in front of the medio-tarsal articulation is displaced outwards. The scaphoid is thus partly dislocated from the head of the astragalus, which projects at the inner side of the foot, and being pressed upon, is often a source of much pain. The transverse ligamentous structures that bind together the bases of the metatarsal bones at their digital ends, become weakened and stretched. The consequence of this is, that the gait loses its elasticity, becomes shuffling and the foot easily tires in walking.

The *Treatment* consists, in the first place, in improving the general health, and removing the causes of over-fatigue or strain in the foot without which surgical treatment will be unavailing. The anterior part of the foot may be strapped firmly with plaster spread on wash-leather. The boots must be carefully attended to. They must be wide at the toes and the heel, must be large and made to extend on the inner side to a point opposite the middle of the foot. The boot must be fitted with the so-called "surgical sole," that is, to say, a pad must be placed inside to support the arch. This must be made of cork, or better still of India-rubber, and must not be too stiff or too large. The upper leathers of the boot must be strong, reach well above the ankle, and be laced firmly. If the feet are habitually cold, they must be rubbed twice a day with salt and water and warmly clothed. These measures will suffice at least to arrest the progress of the deformity. In very extreme cases it may possibly be necessary to apply an iron similar to that represented in Fig. 524, but without the spring for flexing the ankle. This is, however, seldom required, and should always be avoided if possible. A light elastic spring may sometimes be fitted in the side of the boot in such a way as to direct the foot slightly inwards.

Hollow Club-foot.—As in the hand, so in the foot, the interosseous muscles not only move the toes laterally, but powerfully flex the first phalanges, at the same time that they extend the last two. In paralysis of these muscles, and of the short flexor and adductor of the great toe, the toes assume the constrained position of a claw, i.e., the first phalanges are extended upon the metatarsal bones, and the last two phalanges flexed upon the first. This gives rise to a variety of club-foot which Duchenne calls "hollow claw-foot." This is often complicated by paralysis or atrophy of some of the muscles of the leg, giving rise to various associated forms of club-foot.

The accompanying drawing (Fig. 648) shows, 1st, that the first phalanges are extended almost to the point of being subluxated upon the heads of the metatarsal bone, whilst the last phalanges are flexed upon the first and thus a claw; 2d, that the curve of the plantar arch is considerably increased. The origin of this hollow claw-foot or *pes cavus* is as follows:

"When the interosseous muscles are paralyzed or atrophied, the pre-contraction of the muscles which extend the first phalanges and that of the muscles which flex the last phalanges being no longer opposed, the convex condition of the toes gradually becomes augmented. The posterior extremities of the first phalanges are subluxated upon the heads of the metatarsal bones, then the curve of the plantar arch becomes increased and the plantar fascia shortened; then certain articulations and their ligaments become deformed, as in all club-feet." The mechanism is exactly the same as that of the similar disease in the hand.

This disease makes standing and walking very painful when too prolonged, for this reason, that from the position of the toes and from the increased arch of the foot, the whole pressure in walking is borne upon the first and

upon the skin covering the unnaturally prominent heads of the metatarsal bones, which latter become tender in consequence, especially that over the great toe.

In the case from which the drawing was made, the disease was congenital, but did not trouble the patient till he was ten years old. When he was apprenticed, a long walk always gave him pain, and at last he was obliged to lie up about one week in every month to get rid of his pains. Both feet were affected, but the left much less than the right. By galvanic examination, irritability was found to be entirely lost in the right interossei and very much diminished in the left.

The disease is always accompanied by a tendency to talipes equino-varus, "that is to say, the flexion of the foot upon the leg during walking is incon-

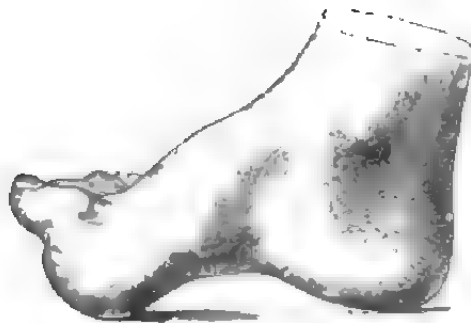

Fig. 648.—Hollow Claw-foot, pes cavus.

plete, and during this flexion of the foot the tibialis anticus (flexor adductor) has a predominance of action over the extensor longus digitorum (flexor and abductor of the foot); or, in other words, during flexion the sole of the foot is turned slightly inwards and the dorsum outwards." This is accounted for by considering the unfavorable conditions in which the long extensor of the toes is placed after paralysis of the interossei. The inferior attachment of this muscle is upon a movable point, the posterior and superior extremities of the second and ungual phalanges. The tendency to extension is counteracted by the interossei, which serve to give a fixed point for the extensor longus digitorum to act from, when flexing the foot at the ankle. But when these muscles are paralyzed, the attachment of the extensor communis digitorum becomes very movable, and we then see at the moment of flexion of the foot upon the leg, that the first phalanges are drawn back even more than before upon the metatarsal bones, at the same time depressing the heads of these bones. The action of the long extensor as a flexor and abductor of the foot is thus much weakened, and this leads to a predominance in the action of the tibialis anticus (flexor and adductor of the foot), in consequence of which a mild form of varus is produced accompanied by some raising of the heel, due to imperfect flexion of the ankle-joint.

To sum up: this variety of hollow foot (*piéd creux*) is produced by an exaggerated and continued action of the extensors of the first phalanges of the toes—extensor communis digitorum and extensor proprius pollicis, following on a weakness or feebleness of their antagonists—the interossei, adductor, and short flexor of the great toe. Consequently any excess of action of these same extensor muscles, whatever may be its cause, ought to produce exactly identical results.

The knowledge of this fact explains the origin of the hollowed claw-foot that we see produced in talipes equinus, when the long extensor of the toes

has preserved its voluntary contractility; and it will be as well here shortly to consider the cause of the alteration in the foot in *talipes equinus*. As soon as the *talipes* commences to oppose the flexion of the foot upon the leg, the opposing muscles act with increased vigor to prevent the deformity. This leads to an abnormal extension of the first phalanges of the toes to which the *extensor longus* and *extensor pollicis* are attached, and ultimately to a subluxation of these phalanges upon the dorsal surfaces of the heads of the metatarsal bones. Every attempt at flexion then depresses the heads of the metatarsal bones into the sole of the foot, so increasing the plantar arch. This is most marked in the great toe. The tonic force of the antagonists to the extensors is unable to withstand the exaggerated action of the long extensors.

That the mechanism here given is correct, may be shown by the following fact: In a well marked case of a patient affected with a "hollow claw footed equinus" (*griffe pied creux équin*), we should see that any attempt to flex the foot at the ankle leads only to further extension of the toes, which become drawn back over the heads of the metatarsal bones, pressing them down and increasing the arch of the foot. Hence, so far from any raising of the extremity of the foot taking place, it is rather depressed.

The *Treatment* of this condition must be conducted on two principles: 1. The stimulation of the paralyzed interossei, adductor, and short flexor of the toe by means of faradization; and 2. The division of the tendons of those muscles which by their tonic contraction maintain and increase the deformity. Those which I have usually found it necessary to divide are the *extensor* of the great toe, the *tendo Achillis*, and in addition to these a very tight band of the inner division of the plantar fascia. The Scarpa's shoe that is used after the operation should have hinges across the middle and be provided with a rack-and-pinion movement, so that the depressed heads of the metatarsal bones may be raised by the anterior half of the sole. In some of the slighter cases the instrument here represented (Fig. 649) may be used to obtain the extended position of the toes without division of the tendons.

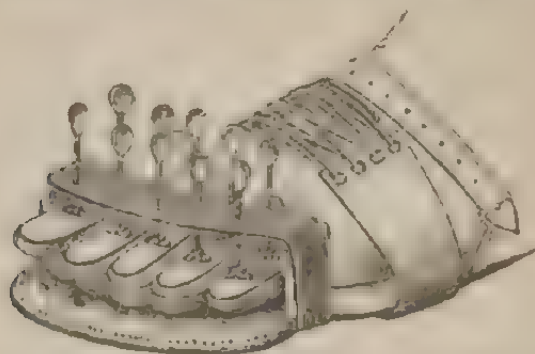

Fig. 649.—Apparatus for obtaining Extension of Toes without Division of Tendons.

Contraction of One Toe is not of unfrequent occurrence. In this complaint the proximal phalanx is either on its normal level or slightly drawn up; the two distal are bent down at an acute angle, the apex of which is formed by the articulation of the first with the second. This contraction more commonly affects the second toe, is often symmetrical in the two feet, and is frequently a source of great inconvenience, and even permanent lameness. It appears to be due to contraction of the digital prolongation of the

plantar fascia, and is best remedied by dividing this subcutaneously opposite the lower part of the second phalanx, and then straightening the toe.

Supernumerary and Webbed Toes are sometimes met with. It is comparatively seldom, however, that any operative interference is required in these cases. Should it be, the remarks that have been made at pages 506 and 507,

Congenital Hypertrophy of Toes and Foot.

Fig. 650.—Plantar Aspect. Fig. 651.—Dorsal Aspect.

in reference to the treatment of these conditions in the hand, are equally applicable here.

Congenital Hypertrophy of the Toes and Foot, as represented in Figs. 650 and 651, occasionally occurs. This malformation is of necessity incurable.

Weak Ankles not uncommonly occur in rickety children; the ligaments being relaxed, the joints appearing to be swollen, and the child being unable to walk or stand without great difficulty. In these circumstances, attention to the state of the general health, douching with salt water, with the application of an elastic India-rubber bandage round the ankle, or the use of light iron supports, will be found most useful.

DISEASES OF REGIONS.

CHAPTER LV.

DISEASES OF THE HEAD AND NECK.

DISEASES OF THE SCALP AND SKULL.

The Scalp is subject to all those surgical diseases that affect the common integument of the body. But it is more than any other part of the surface liable to two diseases, viz., Atheromatous Cysts and Nævi. These have already been so fully treated of—Cysts, p. 931, vol. i.; Nævi, p. 953, vol. i.; and p. 93, vol. ii. that their description here would lead to needless repetition.

Pachydermatous Tumor of the Scalp or Molluscum Fibrosum (vol. i. p. 944). This disease, of extremely rare occurrence, was first described by John Bell. It was first named and fully described by Valentine Mott as

Pachydermatocoele, more recently by Virchow as *Fibroma Molluscum*. The accompanying cut (Fig. 652), taken from a patient whilst in America, who was afterwards successfully operated on by W. Stokes, in Dublin, gives a good representation of the disease.

These tumors are neither painful nor dangerous, but their weight and the deformity occasioned by them render their removal desirable.

Treatment.—The removal of this tumor may be effected by the ligature or the knife. Pollock has successfully extirpated one by the former, W. Stokes by the latter method. But the operation is not without danger. In Stokes's case the hemorrhage was described as terrific, nearly costing the

patient his life, and had to be arrested by the cautery. Stokes states that in the whole course of his experience he had never seen such copious and uncontrollable "weeping" hemorrhage; it came from every point of the cut surface.

Fungus of the Dura Mater.—Sometimes without external or apparent cause, at other times in consequence of a blow or fall, a *Fungous Tumor*

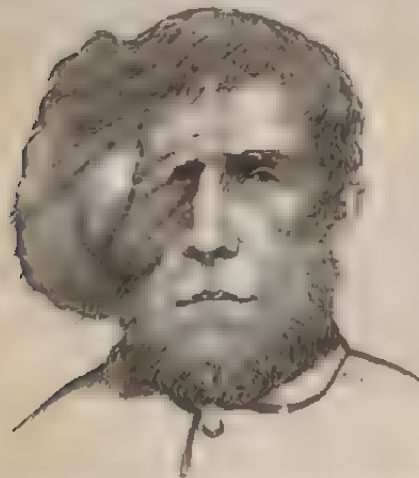

Fig. 652. Pachydermatous Tumor of the Scalp.

grows from some part of the dura mater, usually on the top of the head or in one of the parietal regions. As it increases in size, it produces absorption of the skull covering it: the bone becomes thin and expanded, and crackles like parchment on pressure, sometimes not being raised above its proper level, but more usually being pushed up by the pressure of the growth beneath, which at last protrudes under the scalp. More usually, this perforation of the skull is gradual; but in some cases it would appear to have been rapid, the first intimation of disease that the patient had being the presence of a tumor under the scalp. When the skull is perforated, the sharp edges of the circular opening can be distinctly felt; and the tumor which protrudes pulsates distinctly, as may be proved both by the finger and the eye.

Pathology.—The nature of these tumors is somewhat uncertain, as sufficient cases have not yet been recorded with an accurate microscopical description of the growth: but it is probable that in the majority of cases they are made of spindle-celled sarcomata springing from the outer layers of the menbrane, which forms the internal periosteum of the skull.

Symptoms.—Symptoms of cerebral disturbance—double vision, optic neuritis, loss of sight, deafness, or epileptic fits, with fixed pain in the head—usually precede for a considerable time the external appearance of the tumor. In some rare cases, no such symptoms have indicated the existence of intracranial disease, and the first evidence of the disease has been the sudden protrusion of a pulsating tumor through the skull. If the tumor be compressed, egg shell crackling of the expanded and thinned cranial bones will be heard, and if attempts be made to push it back under the bones, giddiness, vertigo, and convulsions are produced. As the disease makes progress, death from paralysis and coma supervenes.

Treatment.—The result of the treatment of fungus of the dura mater is not satisfactory: yet, as the disease appears to be almost of necessity fatal if left to itself, something should be attempted—not, however, until the tumor has fairly appeared through the bones. The scalp covering it should be turned back by a crucial incision, and the tumor exposed. The aperture in the skull through which it is protruded may then, if necessary, be enlarged by the use of the trephine or Hey's saw, so as to lay bare the full extent of the tumor, which must then be carefully dissected away from the dura mater. In a case in which the operation was being performed by Volkmann, the patient died from the entrance of air during inspiration through an accidental wound of the longitudinal sinus.

Fungus of the Skull also may occur. This term has been applied to any elongating tumor springing primarily from the vault of the skull. The growth may spring from beneath the periosteum, when it is usually a small rounded or a spindle-celled sarcoma, or from the diploe when it is most commonly myeloid. It gives rise to a smooth ovoid tumor on the head, which may or may not pulsate. If it springs from the diploe it is usually covered by a thin layer of bone, which gives the sensation of egg shell crackling, when it is subperiosteal, it not uncommonly contains a framework of jagged spicula of bone. As the disease progresses it usually perforates the skull, and comes into contact with the dura mater. It is then very difficult to determine whether it arose from that membrane, or merely implicated by extension. These tumors may become multiple, and after a time be followed by secondary visceral growths. I have twice seen the liver particularly affected in this way, death resulting without cerebral disturbance or intracranial hemorrhage and exhaustion. The only treatment possible is removal of the growth but this is accompanied by considerable danger not on account of the perforation of the skull and implication of the dura

mater, but from their extreme vascularity. In a case of this kind, which I had an opportunity of seeing many years ago, the growth was successfully removed by B. Phillips.

Secondary sarcomata and carcinomata are also occasionally met with in the bones of the skull. In a case recorded by Morris a few years ago, a large pulsating tumor of the skull was found to present the structure of the thyroid gland, and was apparently secondary to an enlargement of that body. Three or four similar cases have been recorded by other Surgeons.

Hernia Cerebri, arising from wound or ulceration of the dura mater, has been already described (*see* vol. i.).

Congenital Hernia of the Membranes of the Brain is sometimes met with in the form of **Meningocele** or of **Encephalocele**. In the former, the protruded sac is filled with fluid; in the latter, it contains also cerebral substance. The diagnosis between these two conditions is generally difficult; and is of little practical importance. The disease is usually speedily fatal. Z. Laurence finds that, of 39 instances in which it occurred, 21 were males, 18 females; that the protrusion may vary from the size of a pea to that of a tumor exceeding the child's head; and that the occiput is its chief seat—of 79 cases, 53 being in this situation. The hernia may occur at several other points. It has been seen projecting through the anterior fontanelle. In this situation it has most frequently undergone spontaneous cure as the fontanelle closed. Numerous cases have been recorded in which it projected through a deficiency in the region of the cribriform plate into the nasal fossae, or forwards into the face at the root of the nose, the nasal process and the neighboring parts of the frontal bone being deficient. Lichtenburg has recorded a case in which it projected from the base of the skull into the pharynx. In these uncommon situations, the swelling may be mistaken for a polypus. In six of the cases collected by Z. Laurence, the subjects of this malformation reached an adult age; in all the remaining cases they died early, or were stillborn. Surgery offers little in these cases; though in one instance Paget used injection of iodine with success; and in another, where sloughing of a portion of the tumor was taking place, Annandale applied a ligature to the peduncle, and removed the tumor, the child recovering completely in spite of an attack of measles. In another case, the portion of brain was sliced off, the patient surviving.

Tapping the Head.—This operation has occasionally been performed in chronic hydrocephalus, but so far without much benefit. It is sometimes conjoined with pressure by means of an elastic bandage. It is applicable only to those cases in which, from the early age of the child, or the imperfect ossification of the distended skull, it is possible to compress the head by a moderate degree of pressure. The operation is best performed by means of the aspirator. A fine needle may be pushed through the anterior fontanelle or the coronal suture, avoiding the middle line for fear of wounding the longitudinal sinus. The instrument should be directed away from the middle line so as to penetrate the lateral ventricle, and thus to evacuate a portion of the contained serum. There should be no vacuum in the needle when it is introduced, but when it has penetrated deeply enough to reach the ventricle, the piston of the aspirator may be slowly raised, so as to withdraw the fluid gradually, and not to disturb the circulation through the brain. After a moderate quantity of fluid has been withdrawn, the small aperture should be closed with a strip of plaster, and an elastic bandage should be applied round the head so as to compress and to confine the bones. It is scarcely necessary to observe that the prognosis in these cases is not of a very favorable character.

DISEASES OF THE EAR.

AFFECTIONS OF THE EXTERNAL EAR AND MEATUS.—**Malformations** of the lobule are not uncommon. Absence of the pinna or such deformity as completely to close the meatus has also been met with. **Hypertrophy** of the external ear is sometimes met with in idiots; and in gouty subjects, **Tophi**, or **Gouty Concretions**, are occasionally deposited in it. Paget, Bruck, and Vanzetti have described a **Fibrous Tumor** that occasionally forms in the lobule of the ear from the irritation produced by piercing it, as "one of the penalties attached to the barbarism of ear-rings." These tumors are semi-malignant, like the warty growths of cicatrices; and, after excision—their only treatment—are somewhat apt to return.

Bloody Tumors, or **Hæmatomata**, are occasionally developed without apparent cause in the external ear of the insane or idiots, and are not uncommon in other patients as the result of injury. They may attain a large size, and are often multiple. Unless they become inflamed, I think it better to leave them untouched, when they will gradually be absorbed. If inflamed, they must be opened.

Aczema of the External Ear, sometimes extending into the external meatus, is a common affection. It occurs in scrofulous children, and in gouty adults. The constitutional treatment must be conducted on ordinary principles; locally the application of glycerine of borax or of boracic acid ointment, to which a small quantity of extract of belladonna may be added, will be found most useful.

Concretions in the Meatus.—We not uncommonly find that the meatus becomes blocked up by accumulations of wax, dark, indurated, and pipe-like, or forming balls and masses that lie in contact with the membrana tympani. These occur chiefly in individuals of the bilioso-phlegmatic temperament, and are a common source of temporary deafness among young people. They not only materially impair the sense of hearing, but are very apt to give rise to noises in the head, and to crackling sensations on opening and shutting the mouth. Their presence is best ascertained by examination with a well-constructed ear-speculum. The *Treatment* of these concretions consists in softening the wax by the introduction of a little glycerine into the ear for a few nights, and then repeatedly washing out the meatus by the injection of tepid soap and water, thrown in with a large syringe; as the fluid regurgitates from the membrana tympani, it will at length bring away dark and hardened ceruminous masses.

Thickening of the Cuticle.—Occasionally the cuticle of the external meatus, and that covering the membrana tympani, becomes thickened and indurated, assuming a dull white appearance. This is commonly a result of eczema, and may give rise to some degree of deafness. In these circumstances, glycerine, citrine ointment, or solution of nitrate of silver, will be useful in restoring the healthy condition of the part.

Boils or Follicular abscesses are not uncommon in the external meatus. They may arise as a complication of eczema, or as the consequence of irritating discharges from the middle ear. The *Treatment* is to apply hot fomentations to the ear, and, if the boil can be seen, relief may often be given by puncturing it with a small knife.

Diffuse Inflammation of the Meatus, or **Otitis Externa**, is most common in children, and may occur from a variety of causes, amongst which are measles, scarlet fever, eczema or injuries. In some cases the inflammation affects the periosteum, and in all, unless it be checked early, it tends to implicate the membrana tympani. The symptoms are redness and swelling, more or

less completely closing the auditory canal, with intense pain, aggravated in many cases by any movement of the jaw. After a time a purulent discharge escapes, when some relief usually follows. The disease may assume a chronic form with discharge from the ear, forming one of the varieties of otorrhoea. In other cases *abscess fornis*, which may lead to disease of the bony walls of the canal. In some cases the canal becomes closed by the swelling, and perforation of the *membrana tympani* may take place. The *Treatment* in the early stages consists of leeches behind the ear, followed by hot fomentations. If suppuration threatens, the pus must be let out early by a free incision made deeply to the bone with a fine knife passed into the meatus.

Exostoses.—Small exostoses occasionally form in the ear, springing from the bony part of the external meatus. These may cause deafness by completely obstructing the canal. They have been successfully treated by Mathewson, of New York, Field, Dalby, and others, by means of the American dental drill.

Periosteal Thickenings, also, the result of syphilis, are occasionally met with. These usually disappear under iodide of potassium.

DISEASES OF THE MIDDLE EAR.—It is impossible in a work of this kind to give more than the briefest possible description of the methods of examining the middle ear, and of the affections to which it is liable; for fuller information the student must refer to special works.

Method of Examination.—For examining the *membrana tympani* or *tympanum* from the meatus, the ordinary silver ear speculum will be found as efficient as any of the more complicated instruments sometimes recommended. The light must be thrown down it by a concave mirror similar to that used for the laryngoscope. If necessary, the ear must first be carefully cleaned by syringing, and afterwards dried by means of small pieces of absorbent wool twisted round the end of a bit of whalebone or wood. The membrane in health is of a bluish-gray color, and the handle of the malleus can be seen crossing it from above downwards and slightly backwards, terminating a little beyond its middle. The membrane is set at an angle of 45 degrees with the floor of the meatus; but, owing to its concavity looking outwards, a small triangular part below and slightly in front of the end of the handle of the malleus reflects back the light to the eye of the observer, and thus appears as a bright spot. The points to be observed in examining the membrane are its degree of opacity, its color, and degree of vascularity; its curvature, whether too concave, or convex and bulging; and the presence or absence of perforation.

The instrument known as *Politzer's bag* is of great value in examining the condition of the Eustachian tube and the middle ear. It consists of a thick India rubber bag with a blunt nozzle, and is used thus: the nozzle is inserted into one nostril, and both nostrils are then squeezed between the finger and thumb, so as efficiently to close the anterior nares; the patient then takes a small quantity of water into the mouth and holds it tild directed to swallow; at the moment he swallows the bag is squeezed, and the upper part of the pharynx above the soft palate is thus distended with air, and as at the same time the Eustachian tubes are opened by the act of swallowing, the air rushes into the cavity of the tympanum. While this is being done, the Surgeon connects his ear with that of the patient by means of an India-rubber tube about three feet in length, with an ear-piece at each end. He thus hears distinctly the effect produced by the distention of the cavity of the tympanum. The cavity of the tympanum can usually be distended equally well if the patient closes the mouth and pinches the nostrils, and then makes a forced effort of expiration. The following are the chief facts learned from this mode of investigation: In health, the Surgeon hears the air enter the

tympanum and impinge on the membrane with a sharp click, sounding to the patient as a loud crack. If the Eustachian tube is closed by swelling or plugged with inspissated pus or mucus, also filling the tympanum, this will be entirely wanting. If the cavity is filled with tenacious mucus or mucopurulent fluid, a crackling, bubbling sound will be heard both by the Surgeon and the patient as the air enters the cavity. If the membrane is perforated and the Eustachian tube pervious, the air will be heard passing through the aperture.

The *Eustachian Catheter* is useful in treatment rather than in diagnosis. It consists of a small metal or vulcanite tube about six inches in length, with a slight curve at one end and expanded at the other to receive the nozzle of the small India-rubber bag used for injecting fluids or air. On the large end is a ring to show the position of the point while it is in the nose. It is thus passed, the concavity of the curve being turned towards the floor of the nasal fossa, so that the point may not hitch against the turbinate bones, the catheter is passed backwards through the nose till it touches the posterior wall of the pharynx. It is then withdrawn about half an inch, and its point directed outwards and slightly upwards against the orifice of the Eustachian tube. The Surgeon, having his ear connected with that of the patient by the India-rubber tube before described, can then ascertain whether the catheter is in the tube or not by blowing some air through it from a small India-rubber bag.

In order to ascertain the degree of hearing, a watch or tuning-fork is commonly used. The distance from the ear at which the ticking of the watch can be heard is generally taken as the indication of the degree of deafness. If the vibrating tuning-fork or the watch be pressed against the vertex, in health it is heard equally well in the two ears; if one meatus or one Eustachian tube be blocked, the sound will be heard more loudly in the affected ear; if the sound cannot be heard with the instrument in this position, or is heard very imperfectly, the deafness is due to disease of the nervous apparatus of the ear.

The diseases of the middle ear are commonly classed under the following headings. Simple Mucous Catarrh and Purulent Catarrh, and each of these is divided into acute and chronic.

Simple Acute Catarrh is usually associated with catarrhal affections of the pharynx, and is most common in children. It is characterized by acute hyperæmia and swelling of the mucous membrane with increased secretion of mucus. Difficulty of hearing is an early symptom, and in some cases there is intense ear-ache radiating over the side of the head. Noises and throbbing in the ear are seldom absent. Examination of the ear shows the external meatus clear, some redness of the membrana tympani, with bulging in some cases. If left unrelieved, the membrane occasionally perforates, after which cure takes place and the aperture heals, or the disease may become chronic. The *Treatment* in mild cases consists of the application of leeches behind the ear, and hot fomentations externally. At the same time the air should be blown into the tympanum at intervals by means of Politzer's bag; the mucus will usually escape when the air regurgitates from the cavity. If there is much bulging and acute pain, relief can be obtained more surely, and the risk of permanent damage to the ear avoided by puncturing the membrane by means of a small lancet-shaped knife specially constructed for this purpose, or a cataract needle. This operation is easy of performance; the speculum having been passed, and a good view of the membrane obtained, the puncture is to be made at the lower part of the membrane behind the handle of the malleus. The mucus may then be blown out by means of air-douches from Politzer's bag, or through the Eustachian catheter.

ter. The operation is usually followed by complete relief, and the small puncture soon heals, leaving the hearing unimpaired.

Chronic Non-purulent Catarrh is a very common disease and a frequent cause of deafness. Two varieties are described—the dry and moist. Dry catarrh is a term applied to a chronic inflammation of the mucous membrane unaccompanied by any excess of secretion. It leads to thickening of the mucous membrane, and finally causes deafness from immobility of the ossicles. In moist catarrh there are swelling and hyperemia with excessive secretion. It often affects the Eustachian tube chiefly, and may lead to its contraction or closure. If this takes place, the air in the tympanum soon becomes absorbed, and the membrane becomes abnormally concave. Noises in the ears and occasional pain are common. It is most commonly associated with pharyngeal catarrh. This condition is the common cause of so-called Eustachian or throat deafness. The treatment of chronic catarrh is usually not very satisfactory. The general health must be attended to, and the catarrh of the pharynx relieved by astringent applications, as nitrate of silver, glycerine of tannin, etc. At the same time the air must be blown into the tympanum at intervals by Politzer's bag, the Eustachian catheter, or by forced expiration with the nostrils closed. By this means the strain on the membrane is relieved and the mucus allowed to escape. Astringent injections into the tympanum by means of the catheter have been used, but their benefit is somewhat uncertain.

Acute Purulent Catarrh is commonly a sequela of scarlet fever or measles. The symptoms may be acute like those of the acute non-purulent form already described, or perforation of the membrane may occur without any acute symptoms having manifested themselves, the first symptom being the discharge from the ear. After the pus has thus found exit the opening in the membrane may close and recovery take place, but in scrofulous children the suppuration may become chronic. It is very important in all cases of scarlet fever or measles, especially in scrofulous children, to keep a careful watch on the ear, as in many cases the complete destruction of the membrana tympani and loss of the ossicles might be prevented by early incision.

Chronic Purulent Catarrh may arise as a sequel of acute inflammation of the middle ear, or as the result of extension from without in diffuse inflammation of the meatus. In these cases the membrana tympani is always perforated. The symptoms are merely loss or dulness of hearing, with a chronic muco-purulent discharge from the ear, often having an extremely offensive smell. The consequences of purulent catarrh are frequently serious, and sometimes fatal. If unchecked, the disease may lead to necrosis of the small bones, or to their becoming ankylosed and fixed by adhesions to such an extent as to be useless. The disease probably in all cases extends into the mastoid cells, and here the discharge may accumulate and decompose. Owing to the irregularity of the cavities it may not find a sufficient exit, and an abscess of the mastoid process may form, gradually perforating the bone and appearing beneath the skin. Caries or necrosis of portions of the temporal bone is a consequence of greater gravity. When this takes place pus may form within the skull between the dura mater and the bone. This may be followed by diffuse septic meningitis, or by thrombosis of the lateral sinus, with subsequent softening and disintegration of the clot, giving rise to embolic pyemia. Less commonly an abscess forms in the temporo-sphenoidal lobe of the brain. In rare cases fatal septic infection may take place without any disease of the bone being found after death. The symptoms of these various complications present nothing peculiar and need no detailed description. In strumous children enlargement and separation of the glands behind the jaw is a common complication.

In the *Treatment* of chronic purulent catarrh of the middle ear, the essential objects aimed at are complete removal of the purulent secretion as soon as it forms, and prevention of its decomposition. As the secretion diminishes astringent applications may be used to hasten its cessation. The removal of the purulent secretion is effected chiefly by frequent syringing of the ear, and by blowing through the cavity either by Politzer's apparatus, the catheter, or simple forced expiration. The syringe must not be used too forcibly, especially if the opening in the membrane is large. Hinton recommended that an India-rubber ball syringe with a nipple-like nozzle completely filling the external meatus, should be used, by means of which the fluid may be made to flow through the ear into the pharynx. This should be done with steady gentle pressure. If too much force be used, it causes giddiness or faintness. The head should be held forwards, so that the fluid that enters the pharynx may pass out at the nose. Decomposition is prevented by the use of antiseptic solutions, the best being Condy's fluid, chloride of zinc (gr. j to ʒj), or a concentrated solution of boracic acid. After the ear has been syringed the meatus should be carefully dried with cotton-wool. In many cases great benefit is obtained from blowing into it a small quantity of iodiform.

Under this treatment the discharge in most cases gradually ceases, and unless it be too large, the opening in the membrane heals. In exceptional cases in which there is insufficient exit for the discharge it may be necessary to enlarge the opening in the tympanic membrane to allow of more perfect cleaning of the cavity.

The complications of chronic purulent catarrh must be prevented if possible by the above treatment. Necrosis of the petrous portion of the temporal bone, meningitis, intracranial suppuration and pyæmia, when they arise, are beyond the reach of treatment. Necrosis of the mastoid process is less dangerous; the sequestrum may separate and be removed by the meatus or externally. If there is pain, redness, and oedema over the process, indicating pent-up pus in the mastoid cells, trephining is sometimes required. It is only necessary to use a trephine when the bone is very hard. As a rule, the outer layers can be cut away with a small gouge, after which the mastoid cells can be broken into with a strong probe. The opening should be made a quarter to half an inch behind the attachment of the auricle, and on a level with the upper margin of the external meatus. The instrument must be directed inwards and slightly forwards. The operation must be performed with great caution, to avoid any risk of wounding the dura mater or the lateral sinus. This operation must be reserved for cases in which the pain, swelling, and tenderness over the process lasting for some time clearly indicate an accumulation of pus. If carefully performed, it can do no harm and may do much good.

The constitutional treatment consists in the administration of cod-liver oil, iron, and tonics, as the case may require.

Otorrhœa.—This is merely a name for muco-purulent discharge from the ear. As already pointed out, it may arise from diffuse inflammation of the external meatus, from badly treated abscess of the meatus, from catarrh of the middle ear with perforation of the membrana tympani, and from disease of the petrous portion of the temporal bone or mastoid process. Disease of the bones of the ear is very rarely primary, being almost always a secondary consequence of disease of the mucous membrane. The treatment has been already described.

Polypus.—Polypi of the ear, in the great majority of cases, spring from the tympanum, and project through an opening in the membrana in cases of chronic aural catarrh. They are rarely met with springing from the external

mentous. They are usually hard and fleshy-looking, though sometimes soft and gelatinous, as in the nose; sometimes pedunculated, but at others situated on a broad base. They produce serious inconvenience by obstructing the external ear, and require to be twisted off by means of forceps, or, if too firmly fixed for this, cut off with scissors or a wire snare; after which means must be taken to cure the purulent catarrh upon which the growth is dependent.

Nervous Deafness is recognized by the absence of the symptoms of any of the foregoing diseases, or of the history of their occurrence, and by the fact that a vibrating tuning-fork is either not heard at all or imperfectly heard when it is placed upon the vertex or between the teeth. As it is not amenable to surgical treatment, it is needless to discuss here its causes or pathology.

DISEASES OF THE NOSE.

EXTERNAL AFFECTIONS OF THE NOSE. **Acne Rosacea** is an affection of the skin of the nose, in many cases distinctly resulting from alcoholic excess, in others, especially in women, being apparently connected with chronic dyspepsia. It commences as a red spot on which dilated capillaries are visible, and extends gradually over the whole tip of the nose and often to the adjacent parts of the face. At first the sebaceous follicles are not affected, but later on they usually become enlarged, making the surface more or less tuberculated. Some thickening of the skin usually occurs at this stage. The treatment consists in correcting evil habits in drinking or eating, and attention to the digestion and general health. Locally, iodide of sulphur ointment is useful.

Lipoma Nasi is a chronic hypertrophy of the cutaneous and subcutaneous structures, forming a large reddish-blue, vascular-looking, soft, tremulous,

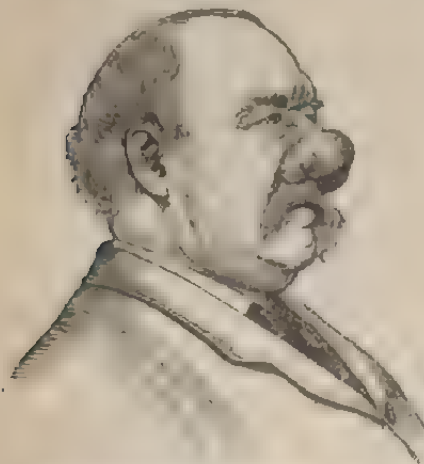

Fig. 653.—Lipoma of Nose before Operation.

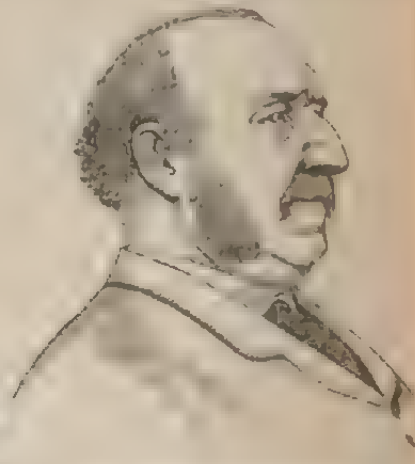

Fig. 654.—Same Nose after Operation.

and lobulated mass, enveloping the end of the nose, and producing excessive deformity of it. There are all degrees of this disease, from mere clubbing of the end of the organ, to the formation of a set of pendulous lobular tumors attached to it. The sebaceous glands are greatly enlarged in this disease, often reaching the size of small peas. The patient's appearance may be greatly improved by the removal of these growths, as is shown in Figs. 653, 654, taken from a patient operated on by M. Beck. This may be done

readily enough by making an incision down the mesial line to the alar cartilages, and then dissecting the lipoma off these on each side; especial care, however, being taken in doing this not to encroach upon the nostril. This is best avoided by directing an assistant to keep his finger in it while the dissection is being prosecuted, so that he may warn the Surgeon of the too near approach of the knife. The surface is then left to granulate and cicatrize.

Lupus, Epithelioma, Rodent Ulcer, and Tertiary Syphilitic Ulceration are all common in the nose. Lupus especially may be looked upon as almost specially affecting this organ, destroying one or both alae, the columna, or perhaps the whole of the nose. The consideration of the nature and treatment of these affections in this situation presents nothing special (see Chapter XXXVII, vol. i.): but the cure of the deformities induced by them, which is full of interest to the Surgeon, will be considered in detail when we speak of the plastic operations that are practised on the face.

Ulcers and Fissures, of a less serious character, though very painful and chronic, often occur at the angle of the ala and septum, or between the ala and tip. Their *Treatment* consists in touching them from time to time with nitrate of silver, or in the application every night of white precipitate or citrine ointment; at the same time that the general health is attended to, and the strength restored, by the administration of iron, bark, and sarsaparilla.

AFFECTIONS OF THE NASAL CAVITY. Examination of the Nasal Cavity. — The nasal cavity may be examined from the front by means of the nasal speculum (Fig. 655). This is introduced so as to dilate the nostril, and a

Fig. 655. — Nasal Speculum.

Fig. 656. Fräntzel's Nasal Speculum.

strong light is then thrown in by means of the laryngoscopic mirror. The speculum shown in Fig. 656, will be found very convenient, as it does not require holding, and thus leaves the Surgeon's hands free. The posterior nares can be examined by the laryngoscope, the mirror being held in the reversed position. The patient is placed in the same position as for examining the larynx (see Diseases of the Larynx), but the tongue is not drawn out. The uvula is then drawn forward with a small curved spatula, or the patient may be told to breathe out. The mirror is then inserted till it is close to or touches the posterior wall of the pharynx. The handle may be slightly bent

with the concavity of the curve towards the tongue. This method of examination, or posterior rhinoscopy, as it is termed, is difficult, and it is said that much is learned from it. The posterior nares can be examined also digitally by passing the finger behind the soft palate.

Deviation of the Septum.—This may be the result of injury or a congenital malformation. It is seldom of any importance, but should it exist to an extent as to obstruct one nostril it may be necessary to remedy the deformity by operation. This may be done by forcibly bending the septum to its proper position by some blunt instrument passed up the nostril. Should this be impossible, the part of the cartilage obstructing the nostril may be cut away, care being taken not to remove so much as to cause sinking in of the nose.

Chronic Catarrh, in the form of a thin watery mucous discharge, lasting for many months, is occasionally met with, more particularly in young women, independently of any structural disease of the mucous membrane. The *Treatment* of this affection consists in the employment of tonics and means calculated to strengthen the system generally, and the local application of astringents, such as tannin, chloride of zinc, etc. But under any plan of treatment this affection is apt to prove rebellious.

Follicular Hypertrophy.—Meyer, of Copenhagen, has described a condition occasionally met with in strumous children, in which there is a general overgrowth of the closed lymphatic follicles situated about the posterior nares and upper part of the pharynx. It leads to more or less complete obstruction of the posterior nares, and is often accompanied by deafness. The condition can be recognized by the nasal tone of the voice, the stoppage of the nose, and by the enlarged follicles being felt with the finger passed behind the soft palate. Meyer recommends that the enlarged follicles should be scraped away by means of a ringed-shaped knife set in a long handle, which can be passed through the nostril and guided by the finger behind the soft palate.

Watery Discharge from the Nose.—Sir James Paget has recorded a case in which a clear watery fluid of a specific gravity of 1004, containing a trace of albumen and a considerable quantity of chloride of sodium flowed steadily at the rate of a drop every five or six seconds from the left nostril. The fluid exactly resembled cerebrospinal fluid. Following the practice of Sir Benjamin Brodie in a similar case, Sir James Paget administered sulphate of zinc internally, and injected the nostril with a solution of the same substance, and under this treatment the discharge ceased. The fluid recommenced six months after a severe blow on the forehead. The patient subsequently died of meningitis, the inflammation being most marked about the under surface of the frontal lobes, but no communication was found between the nasal fossa and the subarachnoid space. In the left antrum, however, were found two broad-based polypoid growths which Sir James Paget believes to have been the source of the discharge.

Ozena.—By the term ozena is meant a chronic muco-purulent discharge from the nose, having a peculiar and most offensive smell. It may arise in some cases without evident cause, and is then called *simple*; but more commonly it is due to *sphilitic* or *strumous* disease in the nasal fossa, accompanied by ulceration of the mucous membrane or necrosis of the bones. The *treatment* necessarily varies with the cause of the disease, and will be discussed with the affections that give rise to it, but from whatever cause it arises the nasal cavity must be thoroughly washed out twice a day at least to remove the offensive discharge. This can be done efficiently only by means of the "nasal douche." This consists of an India-rubber tube about the foot long, to one end of which is fixed a nipple-like nozzle to fit into the

soft palate is curved backwards against the posterior wall of the and shuts off the nasal part of that cavity; the fluid, therefore, at the opposite nostril, thus washing out both nasal cavities and the pharynx above the soft palate. The fluid used should contain pepsin, as Condry's fluid, chloride of zinc gr. j to $\mathfrak{z}\text{j}$.; a concentration of boracic acid, or sulphate of zinc gr. ij to $\mathfrak{z}\text{j}$. After the has been thoroughly cleaned, G. V. Poore recommends the following to be taken as snuff: biborate of soda, nitrate of bismuth, \mathfrak{ss} $\mathfrak{z}\text{j}$; of quinine, gr. x; iodoform, gr. v. The snuff may be used two times a day, care being taken to wash it out thoroughly each day nasal douche.

Ozæna.—A very fetid discharge from the nose will occasionally delicate or stumous children while cutting their teeth, and may for several years. It may arise also after one of the acute specific diseases, especially scarlatina or measles. Sometimes it occurs at a later period, women. The mucous membrane is swollen and red, but the disease is rarely attended by ulceration, although this may take place if the discharge is allowed to accumulate. The Treatment consists in the use of nasal douche, after which some astringent application may be applied. Extract of tannin will often be found of great use. It may be applied by a camel's hair pencil through the nostrils, and in most cases it is also to pass a long brush on a bent stem from the mouth behind the tongue, so as to reach the upper part of the pharynx and the posterior part of the nasal cavity. In young children the teeth and stomach must be attended to.

Thickening of the Schneiderian Membrane.—The mucous membrane of the nose is not unfrequently chronically inflamed, especially in children; that portion of the membrane covering the turbinates becoming thick, soft, and vascular, and projecting like a broad fringed surface. It is usually of a bright red color, and covered with a thin mucus without offensive odor. This swelling at all times produces snoring, a peculiar intonation of voice, but increases in wet weather, and becomes so great as seriously to obstruct the breathing.

It occasionally forms either in the mucous membrane or on the septum, thus may lead to necrosis of the cartilages and bone, separation and flattening of the nose, depression of its bridge, and great deformity.

ease of the antrum, and escape of morbid secretion from this into the cavity of the nose.

The *Treatment* of these conditions must be conducted by the use of the nasal douche, followed by the application of solution of nitrate of silver, sulphate of copper, bichloride of mercury, one to two grains to the ounce; or black-wash. The snuff above mentioned will often be found very useful. In syphilitic cases the general treatment of syphilis must be carried out, iodide of potassium or mercury being administered according to the condition of the patient. In strumous cases, cod-liver oil and iodide of iron are most useful. When necrosis occurs, it must be treated as described below.

Necrosis not unfrequently occurs in the loose bony structures lying in the nasal fossæ or in the nasal bones themselves. In these cases the septum nasi participates in the morbid process, and commonly separates or is perforated.

Necrosis may occur in these situations either as the result of syphilis, the abuse of mercury, or from external injury. I have, however, seen cases, more particularly in women and children, which are not referable to any of these causes, or, indeed, to any other external exciting cause, and in which scrofula was probably the occasion of the disease.

The presence of necrosis may be suspected from the great fetor that infects the breath—the characteristic odor of dead bone being emitted, but in an excessive degree; and its existence may always be positively determined by exploration of the nasal cavities with a probe.

The *Treatment* is simple, and must be conducted on ordinary medical and surgical principles. If the general health be impaired, or if the disease be specific, appropriate alternative constitutional treatment must be adopted. The fetor may be lessened by the nasal douche and antiseptic applications. So soon as the bone is loosened, it must be extracted with polypus forceps, coming away in soft, black, crumbling, offensive masses. There is often abundant hemorrhage after this extraction, but I have only once seen serious trouble result from this cause. The patient, who was of intemperate habits, suffered from extensive destruction of the hard palate and bones of the nose. An attempt was made to remove a sequestrum when a sudden gush of blood took place which rapidly proved fatal, partly by entering the lungs and partly from syncope. If hemorrhage occurs, plugging will in most cases easily arrest it.

In cases of obstinate ozæna in which necrosis is suspected, or in which the sequestra cannot be removed by the nostril, Rouge, of Lausanne, recommends that the nasal cavity should be opened by an incision made from the mouth at the reflection of the mucous membrane from the gums to the upper lip. The cartilages are separated, and the septum cut through with strong scissors sufficiently to allow the upper lip and nose to be pulled upwards for a sufficient distance thoroughly to expose the nasal cavity. By removing sequestra in this way, Rouge cured several cases of most obstinate ozæna. After the operation the nose is replaced, and no scar or other deformity results.

Calculi, or Rhinoliths, are occasionally met with in the nasal fossæ, where they simulate foreign bodies, and may keep up considerable irritation and offensive discharge; and here extraction may be practised with a pair of forceps. But sometimes they are situated under the mucous membrane. In two cases I have dissected round calcareous bodies of this kind, of about the size of cherry-stones, from under the mucous membrane of the ala of the nostril in children.

Epistaxis, or bleeding from the nose, is very common in children and in young people about the age of puberty, more particularly in girls, antecedently to the menstrual period; it may either be active or passive, but is most

usually dependent on congestion of the mucous membrane. But in the adult it is more serious, and it may then be associated with and dependent on two opposite conditions—either on a state of plethora with tendency to cerebral congestion, or on an anæmic and cachectic state, in which the blood is thin, and does not coagulate readily. In the first condition the epistaxis is often connected with congestion of the liver, and, when occurring in the young and plethoric, it is often a salutary relief to the system. But when occurring in anæsthetic, anæmic, and especially aged people, it becomes of very serious moment, and in such circumstances the loss of blood may be so continuous and copious that, unless active means be adopted, a fatal termination may ensue. When epistaxis proves fatal, it is by its constant recurrence. In these cases, I believe, the nasal hemorrhage is always associated with a prostrated and unhealthy state of the constitution, dependent upon chronic disease, mischief, especially chronic Bright's disease, with the contracted kidney and cirrhosis of the liver. The worst and most intractable cases that I have seen have been connected with hepatic disease and jaundice. Epistaxis, in some cases associated with purpura; more rarely it occurs in patients suffering from hæmophilia. It is sometimes a prominent symptom in stricture of the bones of the nose.

Treatment—Epistaxis must not be treated simply as a local disease of the nose. It is usually only a symptom of some constitutional condition or vascular disease that requires remedying before the hemorrhage can be expected to cease. Hence it is of the first importance to treat on ordinary medical principles those states of plethora or cachexy with which it may be associated, or those conditions of disease of liver or of kidney that are met with in persons suffering from it.

In young people, otherwise healthy, and in slighter cases, epistaxis may commonly be arrested by the employment of ordinary domestic means, such as the application of cold to the nape of the neck and forehead; and its return may be prevented by the use of purgatives, or by attention to the proper regulation of the menstrual function.

In plethoric adults the flow should not be too suddenly checked, especially if the pulse be very hard and incompressible. Should it prove very abundant, dry cupping between the shoulders, and the application of an ice-bag to the forehead, with rest, will be required.

In anæmic and cachectic subjects, and in old people, the hemorrhage is often attended by dangerous consequences, and requires the use of active measures for its suppression. In these cases the following plan should be adopted. The head should be raised, an ice-bag applied to the forehead, complete rest and quietude enjoined, and gallic acid in ten-grain doses, or half-drachm doses of the tincture of ergot, administered at frequent intervals. When the bleeding still be profuse and continuous, a current of cold water may be made to flow through the nose by means of the nasal douche, or the interior of the nose may be sponged out with a solution of perchloride of iron or tannin. If this do not suffice, it will become necessary to plug one or both nostrils. This is best done by means of a plug of prepared sponge, having a quail or a piece of gum catheter passed through it for breathing purposes, and soaked in a solution of perchloride of iron.

Should the hemorrhage still continue, the blood passing back into the throat, and perhaps being swallowed, the posterior nares require to be plugged as well. This operation should, however, be deferred until it becomes absolutely necessary for the preservation of life. Plugs in the posterior nares behind the soft palate are a source of very great distress to most people, and in old persons will rapidly wear out the powers of life by interference with breathing and sleep. I believe that by attention to proper constitu-

tional and by perseverance in other and milder local treatment plug the posterior nares may commonly be avoided. When absolutely it is best done by carrying a long piece of strong whip cord along of the nose through the posterior nares into the pharynx, by Bellocq's sound (Fig. 657), or, if this be not at hand, by threading through an elastic catheter, and carrying this into the pharynx, then the cord as it appears behind the soft palate, and drawing it forward the mouth, at the same time that the catheter is taken out of the nose; this way the string will pass through the nose, round the back of the palate, into and then out of the mouth (Fig. 658). To the centre of

Fig. 657.—Bellocq's Sound.

Fig. 658.—Diagram of Plugging the Nostril of Bellocq's Sound.

of string that hangs out between the lips, a plug of lint, about the first joint of the thumb, or, better still, a piece of compressed sponge be firmly tied; this is then drawn up into the posterior nares by pulling the end of the ligature that hangs from the nose, being guided in its passage behind the palate by the fingers introduced into the mouth. When the string has ceased, it may readily be withdrawn by means of the string that hangs out of the mouth. As the epistaxis is very apt to recur, it is a precaution when the plug is removed from behind the palate, to leave a piece of string in the nose and mouth, which may be knotted and fixed by a piece of plaster behind the ear. In this way the plug may, if occasion require, be readily replaced without the necessity of reintroducing the sound or through the nose, which is often a troublesome operation.

TUMORS OF THE NASAL FOSSAE.

POLYPS.—Tumors of very different structures and composition grow within the nostrils: and to all of these which possess the common quality of being pendulous and blocking up these passages, the term *Polypos* is applied. Thus Surgeons commonly speak of the *Benign*, the *Soft*, the *Gelatinous*, *Mucous Polyp*, as well as the *Sarcomatous* or *Fleshy*, and the *Malignant*. The term, however, should properly be confined to a soft and pedunculated growth; the fleshy and malignant polypi being more various in structure, fibrous, myeloid, or other sarcomatous tumors, springing from the nasal base, or from the ethmoidal and sphenoidal cells.

The true **Mucous Nasal Polyp** is a soft, moist, gelatinous tumor, of a gavis yellow color when lodged in the nasal fosse; but when it descends to the anterior nares, or beyond them, and is exposed to the air, it becomes a reddish-brown or purple tint, and somewhat shrivelled on the surface. It is usually lobulated, pedunculated, or bottle-shaped; and not very vascular except at the root, where it is permeated by thin-walled vessels that bleed freely on the slightest touch. In structure it is soft and homogeneous to the naked eye. If cut across and squeezed, a large quantity of thin fluid flows from it, and the mass becomes reduced to a small proportion of its original size. Mucous polypi are formed by an overgrowth of the mucous and submucous tissue of the nose. They are covered completely by mucous membrane with ciliated epithelium, the cilia of which may be seen in active movement under the microscope after removal. The mucous membrane may or may not contain glands; occasionally the surface is pitted by the orifices of glands of considerable size. The tissue which forms the bulk of the tumor is composed of delicate bands of connective tissue separated from each other by an abundant mucous fluid. Amongst the fibres are numerous either rounded or presenting the stellate form found in true mucous tumors (see *Myxoma*, vol. i. p. 951, Fig. 377). The whole mass is abundantly supplied by vessels. Occasionally polypi are found, growing from the lower part of the nares, covered with tessellated epithelium. The tumor may arise from any point of the surface of the turbinate and ethmoid bones, and has indeed, though very rarely, been observed to project into the nose from the frontal sinuses and antrum. Polypi most frequently grow from the middle spongy bone, sometimes from the inferior turbinate bone, and in rare cases they are said to have been seen springing from the roof of the nares, but never from the septum. The polypi are usually numerous and of all sizes; as they increase they commonly extend forwards into the anterior nares, but, when large, they may be seen to reach into the pharynx, hanging down behind the palate.

Symptoms.—The symptoms occasioned by the presence of nasal polypi depend on the interference with respiration and speech which they occasion. Inspiration through the affected nostril is impeded, the patient being unable to breathe through it when directed to do so; and his speech is thick and nasal. There are coughing and mucous discharge from the nostril, and all these symptoms are worse in damp than in dry weather. On examining the interior of the nose, by opening the nostril widely with the forceps or nasal speculum (Fig. 656), and then directing the patient to blow down, the lower end of the polyp may be distinctly seen, and, if large, will descend to a level rather even beyond the nasal aperture. By the introduction of a probe, the size and extent of the tumor, together with the position of its pedicle, may be readily ascertained. As it grows, it impresses changes on the shape of neighboring bones, producing expansion and flattening of the nose; and interfering with the flow of tears down the nasal duct, occasions a watery state of the eyes, which, together with the change of shape in the features, and the peculiar character of voice and respiration, enables the Surgeon at once to recognize the nature of his patient's disease. Polypi occur chiefly in young adults after the age of puberty; but they are not unfrequently met with at later periods of life.

Their causes are very obscure. Most commonly they are referred either to a blow or to a prolonged catarrh. They are more common in women than in men.

Differential Diagnosis.—1. Mucous nasal polypi may be distinguished from chronic thickening of the mucous membrane covering the spongy bones, by the absence of the latter of any pedunculated growth around which a probe can be passed,

tional and by perseverance in other and milder local treatment plugging of the posterior nares may commonly be avoided. When absolutely required it is best done by carrying a long piece of strong whip-cord along the floor of the nose through the posterior nares into the pharynx, by means of Bellocq's sound (Fig. 657), or, if this be not at hand, by threading the cord through an elastic catheter, and carrying this into the pharynx, then seizing the cord as it appears behind the soft palate, and drawing it forwards into the mouth, at the same time that the catheter is taken out of the nostril. In this way the string will pass through the nose, round the back of the soft palate, into and then out of the mouth (Fig. 658). To the centre of the piece

of string that hangs out between the lips, a plug of lint, about the size of the first joint of the thumb, or, better still, a piece of compressed sponge, should be firmly tied; this is then drawn up into the posterior nares by pulling on the end of the ligature that hangs from the nose, being guided in its passage behind the palate by the fingers introduced into the mouth. When the bleeding has ceased, it may readily be withdrawn by means of the string that hangs out of the mouth. As the epistaxis is very apt to recur, it is a wise precaution when the plug is removed from behind the palate, to leave a loop of string in the nose and mouth, which may be knotted and fixed by a slip of plaster behind the ear. In this way the plug may, if occasion occur, be readily replaced without the necessity of reintroducing the sound or catheter through the nose, which is often a troublesome operation.

TUMORS OF THE NASAL FOSSÆ.

POLYPUS.—Tumors of very different structures and composition are met with in the nostrils: and to all of these which possess the common characters of being pendulous and blocking up these passages, the term *Polypus* is given. Thus Surgeons commonly speak of the *Benign*, the *Soft*, the *Gelatinous*, or *Mucous Polyp*, as well as the *Sarcomatous* or *Fleshy*, and the *Malignant Polyp*. The term, however, should properly be confined to a soft and pendulous mucous growth; the fleshy and malignant polypi being mere varieties of fibrous, myeloid, or other sarcomatous tumors, springing from the bones in the nasal fossæ, or from the ethmoidal and sphenoidal cells.

The true **Mucous Nasal Polyp** is a soft, moist, gelatinous tumor, of a grayish-yellow color when lodged in the nasal fosse; but when it descends into the anterior nares, or beyond them, and is exposed to the air, it becomes of a reddish-brown or purple tint, and somewhat shrivelled on the surface. It is usually lobulated, pedunculated, or bottle-shaped; and not very vascular except at the root, where it is permeated by thin-walled vessels that bleed freely on the slightest touch. In structure it is soft and homogeneous to the naked eye. If cut across and squeezed, a large quantity of thin fluid flows from it, and the mass becomes reduced to a small proportion of its original bulk. Mucous polypi are formed by an overgrowth of the mucous and sub-mucous tissue of the nose. They are covered completely by mucous membrane with ciliated epithelium, the cilia of which may be seen in active movement under the microscope after removal. The mucous membrane may or may not contain glands; occasionally the surface is pitted by the orifices of glands of considerable size. The tissue which forms the bulk of the tumor is composed of delicate bands of connective tissue separated from each other by an abundant mucous fluid. Amongst the fibres are numerous cells either rounded or presenting the stellate form found in true mucous tissue (see *Myxoma*, vol. i. p. 951, Fig. 377). The whole mass is abundantly supplied by vessels. Occasionally polypi are found, growing from the lower part of the nares, covered with tessellated epithelium. The tumor may grow from any point of the surface of the turbinate and ethmoid bones, and has indeed, though very rarely, been observed to project into the nose from the frontal sinuses and antrum. Polypi most frequently grow from the middle spongy bone, sometimes from the inferior turbinate bone, and in rare cases they are said to have been seen springing from the roof of the nares, but never from the septum. The polypi are usually numerous and of all sizes; as they increase they commonly extend forwards into the anterior nares, but, when large, they may be seen to reach into the pharynx, hanging down behind the palate.

Symptoms.—The symptoms occasioned by the presence of nasal polypi depend on the interference with respiration and speech which they occasion. Respiration through the affected nostril is impeded, the patient being unable to blow through it when directed to do so; and his speech is thick and nasal. There are snuffling and mucous discharge from the nostril: and all these symptoms are worse in damp than in dry weather. On examining the interior of the nose, by opening the nostril widely with the forceps or nasal speculum (Fig. 656), and then directing the patient to bow down, the lower end of the polyp may be distinctly seen, and, if large, will descend to a level with or even beyond the nasal aperture. By the introduction of a probe, the size and extent of the tumor, together with the position of its pedicle, may be readily ascertained. As it grows, it impresses changes on the shape of neighboring bones, producing expansion and flattening of the nose: and interfering with the flow of tears down the nasal duct, occasions a watery state of the eyes, which, together with the change of shape in the features, and the peculiar character of voice and respiration, enables the Surgeon at once to recognize the nature of his patient's disease. Polypi occur chiefly in young adults after the age of puberty; but they are not unfrequently met with at later periods of life.

Their *Causes* are very obscure. Most commonly they are referred either to a blow or to a prolonged catarrh. They are more common in women than in men.

Diagnosis.—1. Mucous nasal polypi may be distinguished from chronic thickening of the mucous membrane covering the spongy bones, by the absence in the latter of any pedunculated growth around which a probe can be passed,

by the florid red character of the thickened membrane, and by the fact that the subjects of this thickening are almost invariably strumous children. 2. In *abscess of the septum*, the history of the case, and the fact of the polyp never being attached to this part of the nose, will establish the diagnosis. 3. There is a peculiar malformation, consisting in a *deviation of the septum* to one side, that may at first be a little puzzling; but here the examination of both nostrils, and the discovery of a depression of one side of the septum corresponding to the projection on the other, will reveal the true nature of the case. 4. The *fibrous and malignant tumors* of the nostril will be found to differ sufficiently in consistence and appearance from the ordinary polypi to prevent their being confounded with them in many cases; yet in some instances much care will be required in coming to a definite opinion as to their true nature. 5. In one recorded case a *meningocele* projecting into the nasal cavity was mistaken for a polypus.

Treatment.—The spontaneous separation and expulsion of nasal polypi is of rare occurrence. I have, however, seen one case in which, after the assiduous use of chloride of zinc injections, a very copious discharge of large sloughy polypoid masses took place from one nostril which had been blocked up by them for many months previously, and from which they had even descended into the pharynx.

Nasal polypi may generally be most readily removed by avulsion with forceps; occasionally, but rarely, when they are very large, with a broad base, and especially when they extend into the throat, they require the application of the ligature. In removing these growths by the *forceps*, instruments of good length but very slender construction should be used,—those generally sold are too thick; the interior of the blades should be properly serrated, and have a longitudinal groove, so that the root of the tumor may be tightly grasped. The patient should be made to sit on a rather low chair; and, as there is generally a good deal of bleeding, a towel should be pinned over his clothes, and a basin placed before him to receive the blood and expectorated matters. The Surgeon then, having ascertained by the introduction of a probe, or by means of the blades of the forceps, the situation of the pedicle of the polypus, grasps this firmly and pulls it off with a twisting movement of the hand. He proceeds in this manner, twisting off rather than pulling away polyp after polyp, until the whole of the nostril is cleared, which may be ascertained by examination, and by directing the patient to compress the snout and to blow through the affected side of the nose. The bleeding, which is often very free, stops on the application of cold water. At about the end of a fortnight the patient should be examined again, as it not unfrequently happens that small polypi, which had been prevented from descending into the nares by the presence of the larger ones, now come down and require removal. These procedures must be had recourse to from time to time, until all tendency to fresh formations of this kind has ceased.

The *ligature* is required chiefly for those polypi that pass into the pharynx through the posterior nares. They may best be tied by passing a loop of strong whipcord, by means of a double canula, through the nose; and then, after expanding the noose round the tumor in the throat, and making it grasp its pedicle, knotting it tightly. In some instances the polypi attain a great size, producing absorption of the nasal bones, and of the nasal process of the superior maxilla. In such cases it may be necessary, in order to extract them, to slit up the nose, and clip away with forceps the osseous surface from which they spring.

Fibrous Polypus. Naso-pharyngeal Tumor.—The term fibrous polypus is applied to a fibroma springing, in exceedingly rare cases from the pericosteum of the bones entering into the walls of the nasal cavity, but more

commonly from the base of the skull, especially from the basilar process of the occipital bone and the under surface of the body of the sphenoid. *Fungus polypus* is a disease of early life, seldom commencing before the tenth year or after the twentieth. As the tumor increases in size it gradually fills the upper part of the pharynx, and extends into the posterior part of the nasal cavity. Its surface is lobulated and covered by mucous membrane; it is firm and resisting to the touch. In the earlier stages its form and size can be ascertained only by digital examination from the mouth, the finger being passed up behind the soft palate. In the later stages the tumor may be seen from the nostrils, and may appear below the soft palate, pushing this forward and seriously interfering with deglutition, and finally with respiration. These tumors bleed freely, and may even be fatal directly from loss of blood. Microscopic examination shows that they are composed of fibrous tissue, with a varying number of flattened or out-shaped cells between the fibres. They usually contain large, tortuous, dilated vessels, which form an important feature in their structure that it has sometimes been suggested to term the growth *fibro-angioma*. When these vessels are opened by incision, or in an operation for removal of the growth, they bleed exceedingly freely, being unable to contract or retract, owing to the density of the structure in which they lie.

The *prognosis* is extremely unfavorable. If left unrelieved, they always cause death sooner or later, either by hemorrhage or asphyxia.

The *Treatment* consists in their removal whenever this is possible. When the tumor is pedunculated it may be possible to pass the loop of a galvanic cautery or of a common wire crescent round the pedicle from the nose. This is, however, seldom practicable. Electrolysis is said to have been successfully used in the destruction of these tumors, but its efficacy is somewhat doubtful. The method generally recognized as being most generally applicable at the present day, is removal by means of Paquelin's red-hot knife; but in order to do this, it is necessary to expose the tumor fully, and several plans have been suggested of doing this, of which the following are the most important. When any cutting plan is adopted, it is always safer, as great hemorrhage may be expected, to do a preliminary tracheotomy and to plug the trachea with Trendelenburg's obturator, or to pass a large sponge into the pharynx, otherwise death may be caused by entrance of blood into the lungs.

In 1862, Sir William Lawrence exposed the nasal fossæ for the removal of polypus by carrying an incision round the nose, commencing on one side external to the lachrymal sac and terminating at the same point on the other side, passing below between the alæ nasi and the upper lip. The alæ nasi were then separated from the bone and the nasal process of the superior maxilla divided in the incision with cutting-pliers. The septum being then divided the nose was turned upwards towards the forehead. The nasal cavity is thus very fully exposed, and the space obtained may in some cases be sufficient for the removal of a naso-pharyngeal tumor of considerable size.

Butcher recommends a somewhat similar operation, but carries his incision in the opposite direction, commencing at the ala on one side, passing up the side of the nose to the level of the lower margin of the orbit, then across the bridge and down the opposite side terminating at the ala. The nasal bones and the nasal process of the superior maxilla, so far as it is concerned in the tumor, are then cut through with a fine saw and the nose turned downwards, in which the upper part of the nasal cavity is very fully exposed. In both these methods the nose is replaced after the operation, and very little deformity results.

Rouge's operation (p. 544) might, in some cases, give sufficient access to the nasal cavity.

Munne, of Avignon, in 1711, attempted to reach these tumors from the mouth by dividing the soft palate. Nélaton extends the operation thus: a transverse incision is first made across the hard palate at the level of the second bicuspid teeth; from the middle of this a second incision is carried backwards, dividing the soft structures of the hard palate and the soft palate. By means of the periosteal elevator and scissors, the two flaps thus formed are separated from the bone and turned downwards and outwards, out of the way. The exposed part of the hard palate is then removed with a chisel and mallet, and thus the posterior part of the nasal cavity and the upper part of the pharynx are brought very fully into view. After the operation, the flaps are united by sutures, as in the operation for congenital cleft palate.

Complete removal of the superior maxilla by Syme, Flaubert, and others, has been adopted as a preliminary step to removal of the fibrous tumor when of unusual size. Langenbeck and others have performed partial excisions of the upper jaw, with replacement of the bone after the operation. These proceedings are more fully described in Chapter LVII.

All these operations are more or less difficult and dangerous, and should not be undertaken unless the tumor threatens death from its size or from loss of blood, or shows evident signs of active growth. According to Le Fort, fibrous polypi tend to cease growing with the growth of the patient, and partial destruction of the tumor by cauterization or electrolysis will sometimes succeed in arresting the further progress of the growth.

Malignant Nasal Tumors. There is a remarkable, as yet undescribed and to me inexplicable, connection between the ordinary benign nasal polypus and tumors of a sarcomatous or cancerous character, developing as a sequence of the extraction of the polyp in the large cavities and interosseous fissures in the vicinity of the nares. I have several times seen in children and young adults tumors of the above-mentioned character developing rapidly in the orbit, the sphenoidal cells, or behind the superior maxilla after the extraction of perfectly and anatomically benign nasal polypi. The questions to be solved are these: Are these tumors the result of the irritation of the operation of extraction? or are they the primary disease being concealed and undeveloped in the deep cavities of the face, the benign nasal polyp being secondary in reality, though more apparent, and consequent to the irritation set up by the graver and yet latent tumor? In whatever way future investigators may answer this, the fact remains certain, that a connection does exist between the two forms of disease. I have several times observed it.

Tumors of rapid growth, malignant in their course (sometimes called malignant polypus), either epithelioma or sarcoma, occasionally form primarily in the middle of the nasal cavity or about the posterior nares. They grow rapidly, with great expansion of the bones, much discharge, often intense pain, and bleeding, the hemorrhage being often excessive. They attack children and persons advanced in life. A tumor of this kind may be developed in different situations. Thus, in some cases, it extends into the pharynx behind the soft palate; in others it has a tendency to press against and absorb, and protrude through the nasal or lachrymal bones, occasioning obstruction of the nostril, divergence and protrusion of the eyeball, with disturbance of vision, and severe neuralgic pains in the head and face. A gelatinous tumor that projects at the inner side of the orbit, extending into the nose and some little distance down upon the cheek, absorbing and destroying the bones on which it lies, and giving rise to secondary deposits under

the angle of the jaw, will soon show its true nature. These diseases, especially when occurring in young people, speedily prove fatal. Death may occur in various ways, according to the nature of the growth and the direction of its development; by exhaustion from hemorrhage; by the implication of the brain and its membranes; by asphyxia; or by constitutional debility.

Treatment—It is seldom that anything very effectual or permanent can be done by operation; and it should be borne in mind, that some of the malignant growths which project into the nostrils take their origin from the sphenoidal or ethmoidal cells, or even from within the cranium, and that the nasal portion is only the external protrusion, as it were, of a deeply seated tumor. Should the tumor be slow in its growth, with an absence of secondary deposits, the Surgeon may endeavor to extirpate it by laying open the side of the face freely, making an incision from the inner angle of the eye down the side of the nose, and then across the cheek, dissecting up the triangular flap, cutting across the superior maxilla above the line of the alveolus, with a narrow-bladed saw and cutting pliers, and then in a similar way into the orbit beyond and through the nasal bones, and the nasal process of the superior maxilla above the tumor, and thus extirpating the growth. In this operation there is often free bleeding, which may be arrested by the actual cautery, and by pledgets of lint soaked in the perchloride of iron, which have the additional advantage of destroying any portions of the tumor left behind in the irregular and cellular cavities of this region. In other cases it may be possible to expose the tumor sufficiently by Ollier's or Lawrence's operation. Whenever the upper part of the pharynx is free, it should be plugged before commencing the operation by a sponge passed behind the soft palate, and in the way already described (p. 544). It must not be too large, lest it push the soft palate forwards against the tongue and obstruct respiration.

Naso-orbital Tumors are growths that, commencing in the upper part of the nasal fossa or in the ethmoidal cells, perforate eventually the thin inner wall of the orbit and expand into the interior of that cavity, displacing the eye upwards, downwards, or outwards, in two, sometimes in all three of these directions. Vision is often but little if at all disturbed. The nostril on the affected side is blocked up by a polypoid growth. But the outline of the superior maxilla and of the hard palate is normal, no projection of the bone, in whole or in part, being perceptible. In fact, the disease and the deformity produced by it occupies a part of the face which is above a horizontal line drawn across the cheek on a level with the upper or orbital border of the superior maxilla. The disease always commences primarily in the nose or in the cavities contiguous to it. The extension into the orbit may not occur for many months after its primary development.

It occurs at all periods of life, from early childhood to commencing old age.

At first it may present the ordinary characters of benign nasal polypus.

This is removed, recurs rapidly, is again removed, with much hemorrhage, and then the orbital implication is developed.

The *Diagnosis* of the naso-orbital from the naso-pharyngeal tumor may

Fig. 659. Naso-orbital Tumor.

be made by observing the displacement of the eyeball and absence of all tumor behind the soft palate in the first case; whilst, in the other, the nasopharyngeal, the orbit is intact, the upper part of the pharynx being occupied by a morbid growth, and the superior maxilla possibly pushed bodily forwards or to one side. In the naso-orbital tumor, the deformity is above the horizontal line of the upper edge of the superior maxilla; in the nasopharyngeal, it is below this.

The nature of the tumor varies. It is usually a large or small spindle-celled sarcoma, but it may be epitheliomatous.

Treatment.—The operation for the removal of naso-orbital tumor may be done as follows. An incision should be made from the root of the nose, directly down along the side and round the ala, so as to open the nasal cavity. The soft parts on the orbital side of this cut are then dissected down into the orbit. One blade of a cutting pliers being passed into the nose, along the outer border of the nasal bone, the articulation between this and the nasal process of the superior maxilla is cut through. An oblique cut upwards should then be made across the nasal process of the superior maxilla deeply into the orbit, the cut bones widely separated, and the nose turned completely over to the sound side of the face. The tumor at the nasal side of the orbit may now be felt, the eye being held to the outer side and protected with a retractor. The orbital tumor may now be enucleated with the finger and curved scissors. The nostril is then cleared by means of polypus-forceps. The bleeding should be arrested by plugging; and, after all the morbid growth has been fairly extirpated, the nose should be pushed back and moulded into shape. The soft parts are then brought together with a few points of suture. As in all similar operations, the posterior nares must be plugged to prevent the blood finding its way into the trachea.

Occasionally the disease has extended into the integuments at the inner angle of the eye. Then the operation becomes more complicated. The following cases, operated on by me at University College Hospital, are good illustrations of this operation.

The first case was one of epithelioma, springing deeply from the ethmoidal cells, passing out through the lachrymal bone and the orbital plate of the ethmoid into the orbit, blocking up the right nostril, and extending some way down the cheek, overlying the superior maxilla. It was growing rapidly in a woman 44 years of age, and required extensive removal of the bony structures in the situation from which it sprang.

The next case was one of a woman 64 years of age, in whom a sarcoma developed with great rapidity in the situation of the lachrymal sac, invading the nose and orbit, and destroying the upper and inner part of the superior maxillary bone. The eye was pushed outwards, the eyelids became implicated in their nasal third, and an ulcerated opening formed over the centre of the tumor. Its growth was attended by very severe tensive pain. The operation consisted in dissecting away the diseased part of the integument, including the nasal third of each eyelid, then turning down a flap from the cheek and cutting away with pliers the osseous structures, including the inner part of the floor of the orbit, a considerable portion of the superior maxilla, and part of the nasal bones. In order to repair the gap made by the removal of diseased skin at the side of the nose and by the removal of so large a portion of the eyelids, a flap of integument was dissected off the bridge of the nose and glided over the aperture, to the edges of which and to the eyelids it was fixed by metallic sutures. Good union took place, and the patient made an excellent recovery. The immediate effect of the operation in both these cases was to relieve the patient of the agonizing pain.

previously occasioned by the tension in the bones of the face produced by the growth of the tumor.

Boech has described a case, in which the patient, a man aged 78, had a malignant tumor of the size of a fist, occupying the middle of the face. The symptoms at the commencement were those of nasal polypus. In removing it was necessary to cut close to the cribriform plate of the ethmoid bone, and as far back as the posterior nares. A flap of skin was transplanted from the forehead, not so much to form a new nose as to cover in the cavity left. The patient was able to leave the hospital in a few weeks.
